ABSTRACT

This work is concerned with the effect of vessel geometry on the hydrodynamics of fluidisation of a bed of milled iron oxide. The effect of going from a cold model representative of a typical pilot plant reactor to one simulating a semi-commercial unit is quantified, and various reactor internal configurations on the latter are evaluated.

The experimental approach is one based on residence time testing and model fitting with parameter optimisation. A model screening aimed at identifying the most reasonable modelling approach is included, and altogether seven models in two categories are formulated and solved in the dynamic mode. Three of these models are considered novel at present, along with the dynamic solutions to two of the others.

The residence time technique involves methane as an inert tracer in air, and continuous analysis of gas withdrawn from the bed via sample probes by a pair of flame ionisation detectors. The process stimulus is governed by a pseudo-random binary sequence, and correlation analysis is employed for noise reduction. A Fourier transform routine, developed from first principles, converts a pair of correlation functions to a process frequency response, and model predictions are compared with the experimental data in this form. Two parameters per model are fitted, and the residual error at the optimum parameter combination provides a

means of identifying the best-fitting model. The optimised
parameters of this model are regarded as estimates of those of
the actual process.

Five models compete in the first screening category. Four of
these have appeared in the literature in one form or another,
and the fifth is novel in that it accounts for axial mixing in
the bubble phase by employing multiple plug flow units. This
model, referred to as the multiple bubble-track or MBT model, is
shown to fit the experimental data better than any of the other
models in both bubbling and slugging systems. This suggests that
employing multiple plug flow units in parallel for the bubble
phase is mechanistically more correct than employing a single
plug flow unit.

The second screening category is related to the situation in
which gas is sparged into an already fluidised bed at some height
above the main distributor. The two models in this category are
both considered novel, and describe opposite extremes of possible
behaviour in one particular sense: one assumes rapid coalescence
between grid and sparger bubbles, and the other none at all. The
laterally segregated bubble phase or LSBP model emerges as the
better process description. The formulation of this model suggests
that physically, bubbles from the sparger tend to retain their
identity as they pass through the bed.

Crossflow ratios estimated on the basis of the best-fitting model
in each category point to the existence of a very strong scale-up

effect. From the shape of the crossflow profiles it appears
that most of the interphase mass transfer occurs in the bottom
meter or so of the bed, and it is suggested that grid design
is the most significant controlling factor. The presence or
otherwise of vertical coils in the bed is shown to have no
significant effect on crossflow, and mass transfer between
sparger bubbles and the dense phase is shown to be similar to
that between grid bubbles and the dense phase.

Finally, it is demonstrated that the axial crossflow profile
in the bubbling bed is consistent with the concept of an
axially invariant mass transfer coefficient based on bubble
to dense phase interfacial area.

NOTES TO THE EXAMINER

This work involves, in certain areas, information which may not be divulged for proprietary reasons. These areas are in particular -

(i)   The exact nature of the powder, including its full particle size distribution.

(ii)   The mechanical details of the multi-orifice distributor and the sparger in the 0.64 m cold model.

(iii) The mechanical details of the dummy coils and supports in the same unit.

INTRODUCTION

The performance of a fluidised bed as a chemical reactor
depends on the reaction kinetics and the quality of gas-solids
contact. For a solid-catalysed, gas-phase reaction the idealised
chemical conversion process may be described as a sequence of
steps or resistances as set out in Figure 1.1. Gas enters the
reactor mainly in the form of bubbles. These bubbles are essentially
catalyst-free, and some of the gas is transported across the bubble-
cloud boundary. This step represents the first resistance (R_1) to
the overall process, and reaction in the catalyst-rich cloud phase
represents the second (R_2). A portion of the gas which leaves the
bubble and enters the cloud does not react in this phase, but is
transported to the emulsion phase (R_3). In the latter phase
reaction occurs as in the cloud phase (R_4).

In general, either the interphase mass transfer or the chemical
reaction could be rate-limiting. In terms of the resistances in
Figure 1.1, overall reactor performance is largely dependent on
the balance between R_1 and R_3 as opposed to R_2 and R_4.

The chemical reaction resistances are functions of local process
conditions and of the catalyst itself. Local reaction rates may
be enhanced or retarded by changing, for example, the catalyst
composition, porosity or temperature. Investigations of this
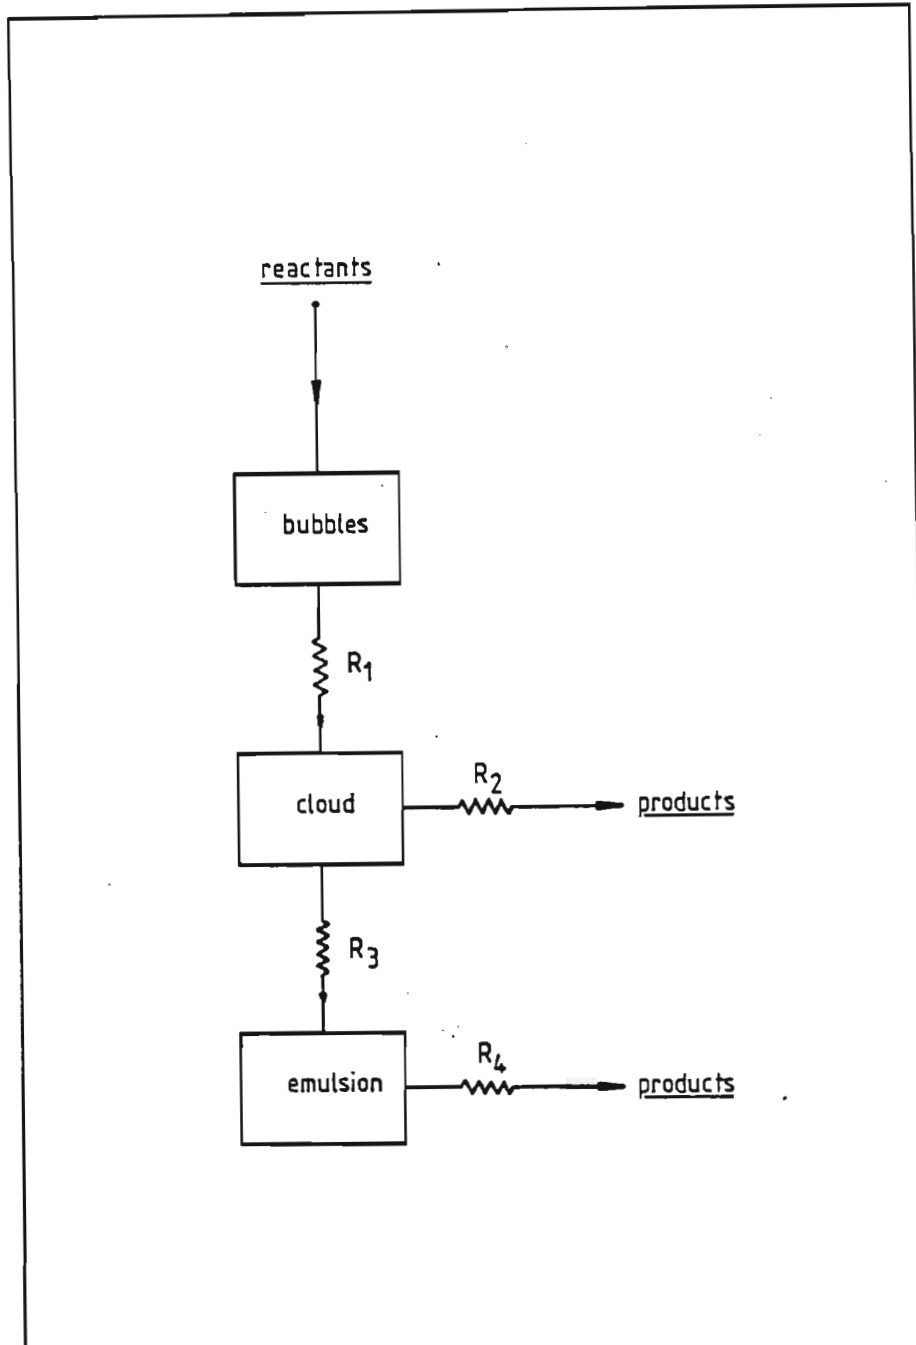

FIGURE 1.1   IDEALISED PROCESS RESISTANCES

nature are usually conducted in laboratory-scale units, and
conditions are often carefully selected and controlled to
eliminate or at least minimise hydrodynamic effects.

A different but related problem facing the practising engineer
is that of scale-up. The chemical reaction resistances are
generally considered fixed in this case, and some idea of how
the hydrodynamic resistances are affected by vessel geometry is
needed. Data from a pilot plant of some type is usually available,
and as such provides the basis for a full-scale commercial design.
The effect of exchanging the pilot reactor hydrodynamics for those
of its larger counterpart need to be accounted for in some suitable
manner - indeed the success or failure of the entire venture could
depend on how well the hydrodynamics of scale are understood.

This study is concerned with the latter of these problems.
The process involves Fischer-Tropsch synthesis in fluidised beds
of fine iron-based catalysts of the type presently used in Sasol's
Synthol process. Small-scale pilot reactors have been successfully
operated for many years, and a research drive is currently under
way to demonstrate the feasibility of this operation in full-
scale units. The work reported here forms an integral part of the
broader research initiative, and is aimed specifically at quantifying
the effect of vessel geometry on the hydrodynamics of the system.

The concept of Fischer-Tropsch synthesis in a fluidised bed is by no means a new one. In order to place the current effort in context and to highlight the need for this study, it is necessary to sketch briefly the history of fluidisation and of this process in particular.

1.1 The Early Years

The world's first commercial catalytic fluidised bed reactor was commissioned at Exxon's Baton Rouge refinery in May 1942. This fluidised catalytic cracker was introduced as a competitor for the existing Houdry fixed-bed process, and its development was undoubtedly spurred on by the increased demand for high-grade gasoline associated with the war effort (1). Design data for this 13300 bbl/day plant was obtained from a 100 bbl/day pilot unit, i.e. a scale-up factor of about 130 (2). Numerous mechanical and materials problems required attention, but the actual process scale-up was relatively trouble-free. So successful was the fluid cat cracker that, two years later, its total capacity in the United States surpassed that of the Houdry units.

Other commercial applications for this form of gas-solids contacting device soon emerged. These included thermal coking, catalytic hydroforming of naptha, iron ore reduction, ore roasting and many more. Amongst these is the Fischer-Tropsch synthesis over iron-based catalysts.

1.2 Fischer-Tropsch Synthesis in a Fluidised Bed

During the war, Germany produced a significant portion of her gasoline and lubricating oil requirements by Fischer-Tropsch synthesis in fixed beds (3). This process was studied in the United States during and immediately after the war, and it was recognised that an enormous increase in space-time yield could be obtained if the fixed bed were replaced by a fluidised bed. This is a result of the strongly exothermic reaction and the higher heat transfer rates attainable in fluidised beds.

In the late 1940's construction began on a 7000 bbl/day plant for the conversion of reformed natural gas to liquid products by Fischer-Tropsch synthesis in fluidised beds. This plant was located at Brownsville, Texas, and design data were obtained mainly from a 0.122 m pilot reactor located at Trenton, New Jersey. The economics of the overall venture were based on conversions obtained in the pilot unit, and it was only once the 5 m commercial reactors were in place and nearly completed that disturbing data from larger pilot units became available. This data suggested that conversion dropped progressively as the reactor diameter was increased. This trend was confirmed when the commercial reactors were commissioned, and for an excellent account of the ensuing modifications and attempts to improve conversion the reader is referred to a paper by Squires (1). Finally, plagued by poor reactor performance and the rising cost of natural gas, the Brownsville plant was forced to close down in 1957.

While the Brownsville experience was in progress, a different
form of fluidised bed reactor for Fischer-Tropsch synthesis was
being developed by the M.W. Kellogg Company. This sytem was
based on a dilute-phase transported or entrained bed, and a
catalyst grind very much finer than that employed at Brownsville.
The concept was demonstrated on a 0.102 m pilot reactor, and
data from this unit provided the basis for the design of the
commercial-scale synthesis reactors built at Sasolburg, South
Africa in the early 1950's. The start-up in this case was
also by no means trouble-free and many practical problems were
initially encountered. The basic concept was sound, however,
as has been borne out by many years of successful operation.

It is against this background that the present research drive
is under way to re-evaluate the feasibility of Fischer-Tropsch
synthesis in a conventional fluidised bed. The potential
advantages of such a system over the existing entrained bed
design are lower capital and operating costs and probably less
maintenance. A demonstration-scale conventional fluidised bed
reactor with diameter a little less than 1 m is presently being
commissioned at Sasolburg. The pilot plant fluidised bed rectors
which Sasol has been operating for 20 years or so have a diameter
of ca 0.05 m, and an understanding of the hydrodynamic differences
between these small units and their larger counterpart could provide
the key to successful operation. Equally important is the effect of
various internals and gas distribution strategies on the effective--
ness of gas-solids contact in the larger bed - hence the aim of the
work described in this dissertation: to investigate the hydrodynamic

differences between a small and a large fluidised bed of fine iron

oxide powder, and to examine the effects of various internal

geometries on the larger of these.

C H A P T E R   2

LITERATURE SURVEY AND AN OVERVIEW

The fluidisation literature has expanded enormously in the past
three decades or so, and has now reached the stage where a complete
review is all but impossible. Given the rather specific objectives
of this study it is clear that certain literary areas are not
directly relevant, so only that material which does have some direct
bearing on the problem at hand will be considered.

By way of a general introduction into the literature on modelling
fluidised bed reactors it is instructive to follow briefly the
historical development of concepts which have led to the current
state of understanding. Before proceeding, however, it would seem
appropriate to give a brief qualitative description of the physics
involved in the process under discussion.

The situation envisaged is essentially one in which gas is passed
upwards through a bed of finely divided solids. If virtually the
entire weight of the solid is borne by the gas rather than by the
walls and base of the containing vessel, the solids are said to be
fluidised. There are some very definite practical limitations to
the range of particle sizes that may be fluidised in this way - if
the particles are too large then the gas velocities required to
support them become excessive. At the other end of the spectrum,
once the particle size drops below a certain minimum, interparticle

forces predominate over body forces and a cohesive mass which
cannot be fluidised in any normal way results. If a fluidised bed
is to be employed as a catalytic reactor it is generally considered
favourable to use a solid which is fine but not cohesive, since
this allows a large catalyst surface area to be present in the
system while proper fluidisation is maintained.

The appearance of a fluidised bed at a gas velocity significantly
above that required to just fluidise it is generally similar to that
of a boiling liquid. Gas voids which are usually referred to as
bubbles are generated at the gas distribution points. They rise
through the mass of closely-spaced solid particles, commonly
referred to as the dense phase, in much the same way as they would
in a liquid. They undergo coalescence and possibly splitting before
bursting at the bed surface, and this overall bubbling action leads
to rapid axial solids mixing. Excellent temperature uniformity is
possible - a very important advantage over the packed bed for
catalytic operations.

When a bubble bursts at the surface of the bed, some particles are
thrust into the above-bed region, i.e. the freeboard. Some of these
particles return to the bed, but others, in particular the finer
ones, are carried out of the system with the gas stream and are said
to have been elutriated. The freeboard region is very often a non-
trivial part of the overall system, since additional gas-solids
contact and chemical reaction is possible in this zone.

2.1   The Historical Development of Modelling

As with most new processes, the earliest modelling efforts were
fairly crude by modern standards. Gilliland and co-workers at
MIT were amongst the first to attempt fluidised bed modelling in
the late 1940's, and Gilliland and Mason (4) reported the results
of gas tracer tests on 1 and 3 inch cold models in the form of a
quasi-Fickian dispersion process superimposed on plug flow. This
approach was not very satisfactory, however, since it failed to
account for the essential two-phase nature of the system. Until
around the end of the 1950's a more general application of gas
residence time distribution (RTD) concepts was also popular, the
principal aim being to establish the degree of gas mixing in the
bed between the extremes of plug flow and perfect mixing.
Gilliland and Mason (5), Dankwerts et al. (6) and Huntley et al. (7)
published studies along these lines, but because the two-phase
nature of the bed was still not accounted for, these results were
applicable to uncatalysed gas-phase reactions only.

In 1952 Toomey and Johnstone (8) made a very significant
contribution: they formulated what is presently known as the two-
phase theory of fluidisation. This theory states that all gas in
excess of that required to bring a bed to minimum fluidisation
conditions passes through in the form of bubbles. It is usually
formulated thus:

$$\frac{Q_B}{A} = U_o - U_{mf} \qquad\qquad (2.1)$$

where Q_B is the volumetric gas flow as bubbles, A is the bed cross-section and U_o and U_{mf} the superficial and minimum fluidisation velocities respectively. A second assumption usually associated with this theory is that the voidage in the dense phase ε_d is maintained at its minimum fluidisation value ε_{mf}, though it is not clear whether the formulators implied this or not.

Application of the two-phase concept led to a very definite improvement in the interpretation of fluidised bed data. Thus, for example, in 1955 Shen and Johnstone (9) applied a two-phase model to the catalytic decomposition of nitrous oxide in a fluid bed, and a year later Mathis and Watson (10) used a similar approach to investigate fluidised catalytic cumene dealkylation. This approach rapidly gained popularity as attested to by the studies of Lewis et al. (11), May (12), Lanneau (13), Gomezplata and Shuster (14) and Van Deemter (15) amongst others. The models used generally described two phases with interphase mass transfer, and in all the studies quoted immediately above other than that of Lanneau (13), this mass transfer parameter essentially had the status of some kind of correlation parameter. Both reaction and gas tracer data were employed, and the general technique was to adjust the mass transfer coefficient for maximum closure between the model and these data.

The next major development in the field of fluidised bed modelling
was the evolution of a link between the physical bubbling behaviour
and the interphase mass transfer characteristics. In 1957 Zenz (16)
put forward a theory describing the gas flow between a single bubble
and the dense $_d$phase, though the main contribution in this area
undoubtedly came from Davidson (17) in 1961. Davidson analysed the
motion of a spherical bubble in terms of the velocity field of
potential flow in an ideal fluid, and predicted gas flow patterns
in and around single bubbles which were soon verified experimentally
(18, 19). The theory was capable of predicting convective cross-
flow between a bubble and the dense phase in terms of minimum
fluidisation velocity and bubble diameter, and even though this
model was subsequently extended by Jackson (20) and Murray (21) to
conform more closely to physical reality, it is its essential
correctness that makes it stand out clearly still today.

Orcutt, Davidson and Pigford (22) were probably first, in 1962, to
interpret fluidised bed data on the basis of a bubble model. The same
kind of two-phase model as that used by Shen and Johnstone (9) was
assumed, but the essential difference lay in the interphase mass
transfer coefficient no longer assuming the role of a correlating
parameter. It was instead specified in terms of a convective
component from Davidson's bubble model and a diffusive component
based on Higbie's (23) penetration theory, and closure between this
model and ozone decomposition data generated by Orcutt (24) was
found to be remarkably good. The basis for testing the model was
bubble diameter: this parameter was calculated from conversion data

(via the model) and also more directly from bed expansion data.

The significance of this development in fluid bed modelling is quite clear: it placed the description of the system on a more mechanistic footing by building into it a recognition of the fact that bubbles exist as individual entities rather than just a "phase" of some kind. It should be noted, though, that the approach is very definitely a two-stage one. In the first stage a two-phase model was assumed, and in the second the interphase mass transfer coefficient in this model was itself modelled in terms of bubble properties. (The reason for drawing the reader's attention to this will become clear in section 2.3.1).

A further refinement in the models used to describe fluidised beds was initiated by the work of Rowe and co-workers at Harwell, England in the early to mid 1960's. In a series of publications (25-27) these investigators showed, amongst other things, that solid particles rise in the wake of a bubble and are deposited on the upper surface of the bed as the bubble breaks through. This led several other groups of workers, of whom Kunii and Levenspiel (28) and Potter and co-investigators (29, 30) are probably best recognised, to postulate a model which describes the resultant solids circulation pattern. This model, unlike the two-phase models used earlier, describes the bed as being divided into three distinct phases: bubbles, a cloud-wake phase and the rest of the dense phase which is often referred to as the emulsion. A very

important feature of this model is the fact that, if the downward
drift of solids in the emulsion (which must exist to compensate
for the upflow in the cloud-wake phase) occurs at a velocity which
exceeds the interstitial velocity, then emulsion gas will be drawn
downwards in this phase.

Since the establishment of the basic building blocks described thus
far, the number of models proposed has increased enormously. It
would seem pointless to pursue the current discussion of develop-
ment along historical lines any further, and rather more appropriate
to switch attention to the current state of affairs.

2.2   Present State-of-the-Art

Any model describing a fluidised bed necessarily contains
a number of assumptions. This section examines each individual
class or subset of assumptions from which an element may, or in
some cases must be drawn in order to allow the construction of a
complete model. Synthesising these assumptions into a complete
picture is deferred to Section 2.3.

2.2.1   Phase Division

The basis of any reactor model is the assumed phase
division, and as with most other aspects of fluidised bed modelling,

several plausible suggestions have been put forward. The earlier
models, as discussed in the previous section, relied mainly on the
simple two-phase theory (8) and accordingly assumed the presence of
a solids-rich dense phase and either a solids-free (e.g. refs. (9,
12, 14)) or a solids-lean (e.g. refs. (10, 11, 13)) bubble phase.
The work of Rowe and others (25-27) and the subsequent introduction
of the Kunii-Levenspiel (28) type of three-phase model opened up
two more possibilities: a division of the bed into solids-rich cloud-
wake and emulsion phases, with either solids-lean or empty bubble
phases. Another possibility is to include a stationary or fixed
phase as has been suggested by Kühne and Wippern (31) amongst others,
though this only really applies to the situation in which gas is
adsorbed onto the solids and effectively removed from any of the other
phases. This variant will not be considered here since adsortption
is not an important factor in the present investigation.

Four common possibilities are shown in Figure 2.1. All of these
have been employed (9, 10, 28, 32), though it could be argued that
they are not quite as independent of one another as they may appear.
The two-phase direct contact model, for example, could be viewed as
a limiting case of the simple three-phase model: a zero mass transfer
resistance beteen the bubble and cloud phases. The three-phase
direct contact model does not appear to have attracted nearly as
much attention as any of the other models, possibly due to the fact
that it offers little advantage over the basic three-phase model in
exchange for a substantial increase in mathematical complexity.

simple two-phase

simple three-phase

two-phase direct contact

three-phase direct contact
FIGURE 2.1   PHASE CONFIGURATIONS

Miyauchi (32) is one of the main proponents of such a phase division
and Miyauchi, Furusaki, Morooka and Ikeda (33) argue that the
presence of some catalyst in the bubble phase is essential if changes
in conversion with changing reaction velocity constant are to be
explained correctly. An important factor to consider when using
such a model is how the solids loading within the bubbles is to be
quantified. Direct measurements have been reported by Lanneau (13)
and Kobayashi et al. (34) amonst others, but very little information
on how this quantity changes in going from one system to another is
available. This suggests the need for repeating such measurements
in each case if an arbitrary assumption is to be avoided.
Alternatively, if the solids loading within the bubbles is to be
regarded as simply a correlating parameter, then the motivation for
its introduction into the model in the first place would require
very careful examination.

According to Grace (35) current modelling tendencies appear to
favour the Kunii-Levenspiel (28) type of simple three-phase division.
This division is perhaps most commonly associated with the so-called
countercurrent backmixing model, and its popularity no doubt owes
much to Fryer and Potter's (36) study of axial concentration profiles
for a reacting tracer. These workers measured a minimum in the axial
concentration profile at a point *within* the bed, and showed that
such a profile could be generated by a three-phase model with solids
circulation.

It is extremely unlikely, though, that a single phase division is most appropriate in every instance. Davidson's bubble model (17), for example, suggests a vanishingly thin cloud when the ratio of bubble to remote interstitial gas velocities exceeds about 20 or so (37). A high velocity ratio is characteristic of fine powder systems, and this suggests that for such systems the cloud-wake phase should be lumped with the emulsion phase, i.e. that a two-phase model is more appropriate than a three-phase one. Grace (38) has developed a similar argument based on Murray's (21) model, and concludes that "cloud models seem to offer no advantages over the simpler models when dealing with small particle systems".

2.2.2   Axial Gas Mixing in the Dense Phase

According to Grace (35), no other feature of fluidised bed modelling has been subjected to as many alternative assumptions. The earliest two-phase models such as those of Shen and Johnstone (9) assumed plug flow and perfect mixing alternatively, and this is also reflected in the earlier bubble models such as those of Orcutt et al. (22) and Davidson and Harrison (39). May (12) was probably first, in 1959, to suggest the use of an axial dispersion parameter, and this approach was also adopted some two years later by Van Deemter (15). Meanwhile, in 1960 Lanneau (13) put forward the idea of downflow in the dense phase, and five years later Mamuro and Muchi (40) proposed the use of ideal mixing stages in series. Shortly afterwards the introduction of the three-phase countercurrent backmixing (29) type

of model imparted some further momentum to the downflow concept,

while Kunii and Levenspiel (28) assumed stagnant cloud and emulsion

phases in the course of development of their mass transfer model.

Since then a number of other suggestions including bubble-induced

turbulent fluctuations (41) have also been put forward.

The relationship between solids movement and dense phase gas mixing

is important in deciding which assumption is most appropriate for a

given system. In particular, when the particles are small, gas-solids

slip in the dense phase is likely to be small and the gas mixing is

likely to be very similar to that of the solids. May (12) recognised

and used this fact: he measured the solids mixing characteristics

using a radio-active tracer technique and assumped the resulting

dispersion coefficients to be applicable to the dense phase gas. The

whole question becomes more complex, however, when one considers the

interaction between solids movement and bubbles. Experiments

carried out by Rowe and Partridge (27) and Gabor (42) suggest that

particles on or near the vertical axis of a bubble suffer a vertical

upward displacement as a result of the bubble passing through, and

based on this observation Haines, King and Woodburn (43) developed

a stochastic mixing model which accounts for such random upward

migration.

Lateral variations in the nature of the bed and the establishment

of gross circulation cells are further complicating factors.

Valenzuela and Glicksman (44) found that lateral solids mixing was

considerably affected by the lateral component of motion of the bubbles, while Potter, Whitehead and Nguyen (45) have shown how gross circulation characteristics depend on bed geometry and gas velocity. When these factors are taken into account, it becomes clear that no simple model is ever likely to describe the dense phase mixing in a fluidised bed with any degree of precision. However, according to Grace (35), the assumption used in describing this mixing process is only really important when conversions in excess of 90% are being considered. This in turn suggests that, for most applications involving modelling the bed as a whole, the selection of a "reasonable" assumption from the list of those already put forward would suffice.

2.2.3 Axial Mixing in the Bubble Phase

The assumptions applied to axial mixing in the bubble phase contrast sharply in number to those applied to the dense phase. This perhaps not too surprising since the bubbles usually move only upwards and backmixing effects are not expected. This suggests that the bubble phase should be treated as a simple plug flow unit, and indeed this is by far the most common assumption.

Shen and Johnstone's (9) models incorporated this feature, and since then little has changed in this particular area - it is probably true to say that this description of the bubble phase is still the most popular one today.

A variation on this appeared in 1965 when Mamuro and Muchi (40) proposed the partitioned model referred to previously. This model assumed a number of ideal mixing stages in series for both phases, with the height of each stage given by the bubble diameter in that stage. Kato and Wen's (46) bubble assemblage model contains a similar description of the bubble phase, as do the more recent versions of this model due to Mori and Wen (47) and Peters et al. (48).

Another assumption which has been employed is that of dispersed plug flow. Wippern et al. (49), Lehmann and Schügerl (50) and Kühne and Wippern (31) are amongst those who have used this approach, and their reasoning appears to be based more on the form of the appropriate two-phase continuity expressions than on heuristic arguments. This approach does, however, carry with it a penalty: in solving such a model an extra boundary condition (BC) is called for at the top of the bubble phase, and there does not appear to be any obvious way in which it should be specified.

Certain investigators have reported the existence of bimodal bubble size distributions in fluidised beds (51, 52): none of the assumptions discussed thus far are capable of describing the bimodal velocity distribution which would presumably accompany such a size distribution. In larger units where the formation of gross circulation cells and preferred bubble paths is possible one might also expect these simple assumptions to become somewhat less appropriate than they might be in smaller units, and the same holds when bubble chains

of the type observed by Werther (53) are present. It would seem
reasonable to suggest that in certain instances an assumption
other than plug flow, dispersed plug flow or stages in series
might be called for - this is taken up again in section 3.2.1.5.

2.2.4   Local Bubble Properties

Bubbles introduced at the distributor of a fluidised
bed usually grow rapidly by coalescence as they rise. This is an
important characteristic of such systems, and a great number of
experimental investigations have been aimed at measuring local
bubble properties and correlating these with the operating
parameters of the system. Such experiments usually involve X-rays
(54), photographing bubble eruptions at the bed surface (55) or
small local bubble probes of some kind (56, 57). The information
thus obtained is generally in the form of individual bubble sizes
and velocities, and bubble growth correlations are most commonly
presented as a variation in average bubble diameter with height
and gas velocity. The nature of the distributor is usually
incorporated into the correlation as either an equivalent height
term or an initial bubble diameter - a few such correlations are
given in Table 2.1.

The relationship between the rise velocity and the size of a single
bubble is fairly well established. It is based on a theoretical
expression due to Davies and Taylor (63) for spherical cap bubbles

AUTHOR	REFERENCE	EQUATION NO.	CORRELATION
Rowe	(58)	(2.2)	$d_b = (U_o - U_{mf})^{0.5} (h + h_o)^{0.75}/g^{0.25}$
Werther	(59)	(2.3)	$d_b = 0.00853 (1 + 27.2 (U_o - U_{mf}))^{0.33} (1 + 6.84h)^{1.21}$
Darton	(60)	(2.4)	$d_b = 0.54 (U_o - U_{mf})^{0.4} (h + 4\sqrt{A_o})^{0.8}/g^{0.2}$
Kobayashi	(61)	(2.5)	$d_b = d_o + 0.14 d_p \rho_p (U_o/U_{mf}) h$
Mori and Wen	(62)	(2.6)	$(d_m - d_b)/(d_m - d_o) = \exp (-0.3 h/D_t)$
			where $d_m = 0.652 (A_t (U_o - U_{mf}))^{0.4}$
			and $d_o = 0.347 (A_t (U_o - U_{mf})/N_D)^{0.4}$ for perforated plates
			and $d_o = 0.00376 (U_o - U_{mf})^2$ for porous plates

TABLE 2.1   BUBBLE GROWTH EXPRESSIONS   (SI UNITS).

in a liquid, and is usually presented thus:

$$U_b \text{ (single bubble)} = \phi \sqrt{g \, d_b} \qquad (2.7)$$

The bubble rise coefficient ϕ is often taken to be 0.71 (39), though Rowe (64) argues that a value of around unity is more appropriate and that this quantity should vary with dense phase voidage. When many bubbles are present in the bed the rise velocity of each individual bubble is commonly assumed to be augmented by the excess gas velocity according to Davidson and Harrison's (39) expression:

$$U_b \text{ (many bubbles)} = (U_o - U_{mf}) + \phi \sqrt{g \, d_b} \qquad (2.8)$$

Rowe (64) has pointed out that little experimental support exists, but this expression has nevertheless been widely accepted. Several modifications have also been put forward. Werther (65), for example, noting that bubbles of the same size rise faster in a larger diameter vessel, has suggested that ϕ should increase with increasing vessel size. Weimer and Clough (66) have suggested the use of what is effectively a distribution coefficient premultiplying the excess gas velocity term to account for lateral variations in bubble concentration.

There is an important factor to bear in mind when considering the application of local bubble size and velocity expressions, and it relates to the existence (or otherwise) of a maxmimum stable bubble

size. If such a maximum does exist in the system under investigation,
then bubbles might be expected to grow only to this limiting size and
to remain more or less constant thereafter. The confidence with
which this maximum may be predicted is perhaps not as great as that
with which bubble growth characteristics may be forecast, and the
theories that have been put forward are decidely at odds with one
another under certain conditions. One of these is due to Harrison
et al. (67), and states that bubbles will break up when their rise
velocity reaches the terminal falling velocity of the particles.
Squires (68) suggested that, for fine powders at least, saltation
off the floor of the bubble is more likely to be responsible for
bubble breakup. For 70 micron FCC catalyst fluidised in air at
ambient conditions these criteria predict maximum stable sizes of
about 0.009 and 1.5 m respectively, and neither embraces Rowe's (69)
observations of splitting by stalactite formation from the bubble
roof.

When bubble growth proceeds unhindered to the stage where the bubble
diameter approaches about one half of the bed diameter, wall effects
become very significant and slugging occurs. This kind of behaviour
is characteristic of small, high aspect ratio beds such as those
used in pilot plants: the conditions under which slugging is
expected have been described by Stewart and Davidson (70). The gas
voids or slugs (for type A behaviour (70)) are elongated and bullet-
shaped, and the velocity of rise is significantly lower than it would
be if the same gas void were present in a much larger bed. Under
these conditions the slug velocity may be assumed to be controlled

more by the diameter of the tube than by any characteristic dimension of the slug itself, and the appropriate analogue of equation (2.8) is:

$$U_s = (U_o - U_{mf}) + 0.35 \sqrt{g \, D_t} \qquad (2.9)$$

Stewart and Davidson (70) adopted this expression from the results of Nicklin et al. (71) for an air-water system, and the slug rise coefficient of 0.35 and the square root dependence can be traced back to the earlier work of Dumitrescu (72).

Slugs need not necessarily rise along the centre of the column - they may also rise along the wall. Birkhoff and Carter (73) pointed out that assymetric slugs might move as if they were in a column twice the actual size, thus giving:

$$U_s = (U_o - U_{mf}) + 0.35 \sqrt{2g \, D_t} \qquad (2.10)$$

Hovmand and Davidson .(74) presented an analysis of slug velocity data from various sources and concluded that equations (2.9) and (2.10) provide a satisfactory basis on which to model such systems. It should perhaps be noted, though, that in view of Rowe's (64) comments regarding the dependence of the bubble rise coefficient on dense phase voidage, one might expected the slug rise coefficient to display a similar dependence.

The type of information discussed here may be used to predict reactor performance in a number of ways. For the bubbling bed case an axial variation in bubble size and velocity could be built into an overall reactor model as in the cases of Mamuro and Muchi (40) and Kato and Wen (46). Alternatively, such information could be used to determine a suitable average for use in conjunction with models such as that of Kunii and Levenspiel (28) which do not account for axial variations. Care should be taken, however, to ensure that the particular expression proposed for use is indeed applicable to the system being studied. The empirical or semi-empirical nature of the bubble growth correlations should be borne in mind and any extrapolation should be treated with extreme caution.

2.2.5 Interphase Mass Transfer

An early estimate of the mass transfer coefficient describing gas exchange between an isolated bubble and the surrounding dense phase was given by Zenz (16) as:

$$(K_{be})_b = 3(\frac{U_{mf}}{d_b})$$
(2.11)

The mass transfer coefficient is presented here in the form referred to bubble volume, and in terms of the three-phase bed division it describes overall, i.e. bubble to emulsion mass transfer. (This

notation is essentially that suggested by Kunii and Levenspiel (28)
and will be used throughout.)

Zenz's (16) expression for interphase transfer is based on the
assumption that gas flows radially through the walls of a bubble at
a velocity equal to U_{mf}. This flow pattern was entirely conjectured,
however, and Davidson's (17) subsequent analysis of bubble motion
led to the following expression for convective crossflow:

$$(K_{be})_b = 4.5 \ (\frac{U_{mf}}{d_b}) \qquad\qquad (2.12)$$

while Murray's (21) analysis led to:

$$(K_{be})_b = 1.5 \ (\frac{U_{mf}}{d_b}) \qquad\qquad (2.13)$$

For the slug flow case similar expressions have been put forward to
describe convective crossflow, e.g.

$$(K_{be})_b = (\frac{U_{mf}}{slug \ length}) \qquad\qquad (2.14)$$

as given by Hovmand and Davidson (74).

A second, diffusive component of mass transfer was derived from
Higbie's (23) penetration theory, and for a bubbling bed Davidson

and Harrison (39) presented the following expression for combined
crossflow:

$$(K_{be})_b = 4.5 \ (\frac{U_{mf}}{d_b}) + 5.85 \ (\frac{gD^2}{d_b^5})^{\frac{1}{4}}$$ (2.15)

This expression was adopted by Kunii and Levenspiel (28) to
describe mass transfer between the bubble and the cloud, and a
further expression was derived from penetration theory to model
cloud-emulsion transfer:

$$(K_{ce})_b = 6.78 \ (\frac{\varepsilon_{mf} \ D \cdot U_b}{d_b^3})^{\frac{1}{2}}$$ (2.16)

Many other expressions have also been put forward to describe
the phenomena under discussion. A broad study of this class of
expression has been carried out by Sit and Grace (75), and
they conclude that the soundest basis for modelling local mass
transfer between isolated bubbles and the dense phase is provided
by penetration theory combined with Murray's (21) expression for
convection, equation (2.13).

These expressions, however, only account for convection and diffusion. Effects such as wake shedding and gas adsorption on catalyst moving past the bubble remain unaccounted for. Another possible effect is that of bubble coalescence - this is a controversial area of investigation, and the conclusions drawn are probably dependent on the exact nature of each system studied. Sit and Grace (76), for example, investigated mass transfer for pairs of interacting bubbles in a two-dimensional bed. They reported a mass transfer enhancement of 20-30% and presented a corrected crossflow expression:

$$(K_{be})_b = 2(\frac{U_{mf}}{d_b}) + 12(\frac{\varepsilon_{mf} \; D \; U_b}{d_b^3 \pi})^{\frac{1}{2}} \qquad (2.17)$$

Pereira and Calderbank (77), on the other hand, reported the total destruction of all bubble to dense phase concentration profiles upon the coalescence of two equal-sized bubbles. This no doubt represents a limiting extreme of some kind, but nevertheless suggests that the conventional mass transfer expressions may not be applicable to systems in which vigorous splitting and coalescence effects are present.

2.2.6   Grid Region and Sparger Effects

For fast reactions, it is well known that most of the conversion can take place in the first half-meter or so of the bed. Ob= servations to this effect have been reported by Cooke et. al. (78) and Hovmand et. al. (79), and both groups of workers found that

conversion was sensitive to grid geometry.

The first step in modelling the grid region is to establish the phase division, i.e. to estimate jet volumes and in particular penetration depths. Several jet penetration corre= lations, similar in principle to the bubble growth correlations discussed in Section 2.2.4, have been published (80-84), though the question of what actually defines a jet has not yet been fully resolved (85-88).

Interphase mass transfer in the grid region was measured by Behie (89). These results were interpreted in terms of Kunii and Levenspiel's (28) crossflow expressions for a bubbling bed, and it was concluded that the mass transfer rate in the grid region is of the order of 50 times greater than that in the bubbling bed higher up.

Several reactor models which account for the grid region have appeared in the literature. These include models for FCC regenerators by Errazu et. al. (90) and De Lasa et. al. (91), and a fluidised bed gasifier model by Weimer and Clough (92). The type of configuration used is shown in Figure 2.2, along with the assumed mass transfer coefficient (MTC) profile. It is apparent that this type of model acknowledges the fact that the mass transfer coefficient is an axially distributed parameter, and accounts for this by employing a two-stage rather than a single-stage model.
FIGURE 2.2   TYPICAL GRID REGION MODEL CONFIGURATION

A closely related problem which has received very little attention to date is that of mass transfer in the vicinity of a gas sparger. Split feed reactors are not uncommon in industry, since this type of configuration is often necessitated by the undesirability of pre-mixing reactant gases. One would expect, in principle at least, that the mass transfer situation would be similar to that near the grid. Several very important questions remain unanswered. For example, how does the nozzle orientation affect crossflow - is it better to direct the nozzles upward, sideways or downward? Another question is how do bubbles rising from below affect the (presumably) small bubbles generated at the sparger? Do they allow the small bubbles to exist in substantial numbers, or do they simply "gobble up" their smaller counterparts by coalescence?

In the context of this study, the question is how one would model a split feed system. A few guidelines are available from grid region studies, but it is clear that the literature is lacking in this particular area.

2.2.7 Disengaging and Freeboard Regions

As bubbles burst at the surface of a fluidised bed, particles are thrust into the freeboard region. The solids holdup decreases progressively from the bed surface to some constant value at and beyond transport disengaging height. Additional gas-solids contact and chemical reaction is possible here as stated previously,

though it is most commonly ignored in reactor models (35).
This effect will not be considered in this study.

A slightly different, but nevertheless related phenomenon has
been observed in the transition region between the bed and the
freeboard. In a slugging bed, Miyauchi et al. (93) reported an
increase in crossflow in the transition region. This is
probably a result of increased turbulence associated with slugs
breaking through the bed surface. The gas escapes rapidly once
the slug has broken through, leaving the solids to fall back
violently along the column walls. This effect is also generally
ignored in the setting up of reactor models.

2.3   An Overview from a Model Classification Point of View

The concept of a general model classification does not appear
to have taken root in the fluidisation literature. In recent
reviews by Potter (94) and Miyauchi et al. (33) complete
individual models only are considered. In the Grace (35)
review individual model assumptions are discussed, but no
attempt is made to identify groups or classes of model beyond
descriptions such as two and three-phase and bubble models. In
an older review Grace (95) refers to the models typical of those
employed in the 1950's as Type I models, and those based on
bubble properties appearing from 1962 onwards as Type II models.
Rowe (96) refers to the same broad classes as "arbitrary two-
phase" and "physical bubble" models respectively, but this is
where the classification ends.

A slightly more comprehensive classification has been suggested
by Horio and Wen (97). According to this scheme Level I models
are the "arbitrary two-phase" models mentioned above, while the
earlier models which do not account for axial variations in
bubble properties are regarded as Level II models. Those which
do account for axial changes in bubble properties are associated
with Level III. Though this classification undoubtedly has its
merits, it is incomplete in several ways. For instance, how
would one classify a three-phase model, such as the countercurrent
backmixing model, if no assumption relating crossflow to bubble
parameters were employed? Also how would one classify a

mechanistic (computer) bubble growth simulation?

A suggestion for a somewhat more general classification is presented in the following section. It should be noted that the author in no way wishes to imply that this classification is complete in any absolute sense, and it is hoped that this classification will serve as a starting point for discussion and development.

2.3.1 A Suggested Model Classification

Before proceeding it is necessary to set out clearly the assumptions and restrictions associated with this classification. These are:

(i)   The analysis applies to the hydrodynamic
        modelling of bubbling or slugging
        fluidised bed reactors only.

(ii)   The reaction kinetics are known and do not
       dominate the overall process.

(iii) It is assumed that a prediction of gas
       conversion is required.

Having stated this, we may now proceed to define four general
classes of model. An overall prediction of reactor performance
involves calculations based on a component drawn from at least
one of these classes, and in most cases several components from
different classes constitute the complete description.

Class A:

A model in this class represents a macroscopic mass
balance description of the system, with parameters
lumped in time and space. This type of model typically
results from writing a material balance over the reactor,
making no assumption on the parameters other than their
spacial and temporal independence. Class A models may
describe any number of phases. The countercurrent back=
mixing model, for example, may be considered class A if
the crossflow parameters are left unspecified - the
commonly employed link between crossflow and bubble properties
is in fact a class C model.

Class B:

This class is essentially the distributed-parameter analogue of class A. Such models also result from an overall material balance, but in this instance the crossflow term(s) and other parameters such as the velocity in the bubble phase are allowed to vary in time and space.

Class C:

Class C models describe local interphase transfer processes: the most well-known is probably Davidson's (17) bubble model. Models describing the transfer from a grid jet to the surrounding dense phase fall into this class, as do models describing interphase transfer when bubbles split or coalesce.

Class D:

Models in class D are those which describe bubble and dense phase parameters as functions of solids and gas properties, operating conditions and vessel geometry. Models in this class do not attempt to describe the interaction between phases - they are confined to predicting properties such as jet penetration depths, bubble size variations with height and dense phase voidages. Class D models are generally empirical or semi-empirical in nature.

Figure 2.3 gives an overall description of how the four classes of model are related and how they can be used to predict chemical conversion in fluidised beds. The diagram also shows the sources of information required by the models, and it is interesting to note that this information can itself be classified into different levels of complexity:

Level 1:

Directly measurable quantities such as superficial gas velocity and particle size distribution.

Level 2:

Quantities describing the holdup and throughflow of gas in each phase. Probes and/or indirect measurement techniques are often called for to obtain information on this level.

Level 3:

Interphase mass transfer coefficients (MTC's). The measurement of these quantities is generally very difficult if not impossible in three-dimensional beds. The use of 2D beds facilitates the acquisition of data on this level, but the hydrodynamics are probably not representative of a 3D system.
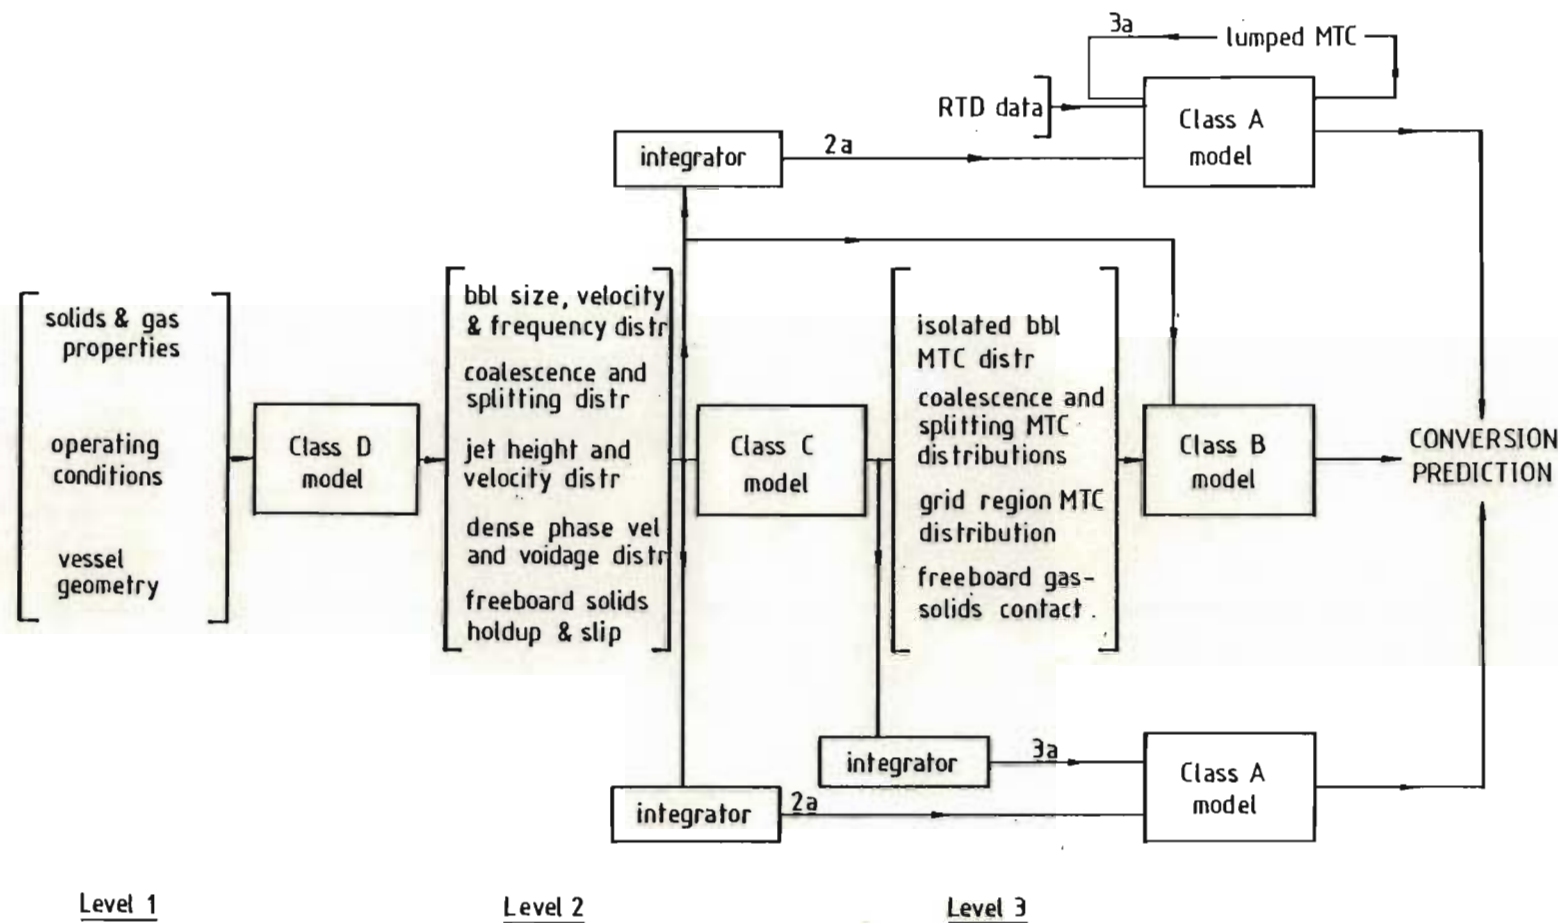

FIGURE 2.3   A PROPOSED MODEL CLASSIFICATION

If the information is averaged in time and space, it is designated level 1a, 2a or 3a. The "a" implies that some suitable averaging has been performed.

In terms of the model classes and information levels defined and the layout shown in Figure 2.3, one could formulate the following "rules":

1. Level 3 information may be measured directly, modelled on level 2 information by a class C model or modelled in two stages on level 1 information by class D and C models respectively.

2. Level 3a information may be extracted from RTD data on the basis of a class A model.

3. Level 3 information may be used to predict conversion by integration (averaging) and subsequent use in a class A model, or directly in a class B model.

These "rules" are essentially nothing new - they are merely statements of known facts in terms of the classification presented here.

As a final comment on Figure 2.3, it should be noted that a complete, unified fluidised bed theory would probably involve

level 1 input data processed by adequate class D, C and
B models respectively. The present state-of-the-art is
probably not sufficiently developed, however, to allow the
general use of this approach with any confidence.

In order to demonstrate the usefulness of the proposed
classification, the author has analysed a number of popular
literature models in terms of component classes. This analysis
may be found in Appendix A.

CHAPTER 3

CHOICE OF METHOD AND MODELS

From the discussion presented in Chapter 2 it is abundantly
clear that several approaches to the problem should be considered.
This chapter deals with a sifting of the various alternatives
and the selection of a suitable technique. Also dealt with is
the selection of a number of models from the literature.

3.1 Choice of Method

With reference to Figure 2.3, there are four possible modelling
strategies. These are:

(i) Class D-C-B/A Route

Level 1 input data is supplied, and a suitable bubble
growth expression (i.e. a class D model) is used to
predict the variation in bubble size with height. A
suitable class C model is then applied and the axially
distributed MTC is used to predict conversion on the
basis of a class B model. An alternative is to average
the MTC in some appropriate manner and to employ a
class A model to predict conversion.

(ii) Class C-B/A Route

Level 2 input data is obtained from some form of
local bubble probe. (It should be noted that an X-ray
technique is regarded as unsuitable due to the nature
of the solids employed). A class C model is applied,
and the resulting MTC is used in either a distributed
(class B) or lumped (class A) form to predict conversion.

(iii) RTD Route

Residence time data and level 2a input are processed
by a class A model to yield a lumped MTC. This MTC,
which may be regarded as level 3a information, is
subsequently used as input to a class A model for the
prediction of conversion.

(iv) Reacting Tracer Route

Chemical conversion is measured under steady-state
conditions for a tracer reacting according to a first-
order rate law. (Kinetics which are non-linear introduce
complicating effects which will not be considered here).

Route (i) involves amongst other things, relying on the
applicability of previously established class D models to the
system under investigation. Some of these models, in
particular the bubble growth expressions such as those of
Mori and Wen (62) or Werther (59), could be applied to this

system without much extrapolation being involved. This would result in a fairly complete picture of bubble size, velocity and (by inference) coalescence distribution throughout the bed, and a class C model could then be applied to these data.

This route was not selected for two main reasons. The first of these is the fact that the maximum stable bubble size, if one does in fact exist, could become very important in modifying the bubble size distribution. The techniques for assessing this maximum stable size, in fine powders in particular, are somewhat less well established than the bubble growth correlations themselves as discussed previously. In a relatively deep bed a small change in particle size distribution of an already fine powder could conceivably have a strong effect on bubble sizes in the upper reaches of the bed - if this change in particle size represented even a small extrapolation in terms of the bubble growth expression (as would be expected here), it is felt that the results would require direct validation before being relied upon.

The second reason is that the established bubble growth expressions do not readily lend themselves to predicting behavior in beds with spargers and vertical coils. Since establishing the effect of such internals was regarded as one of the aims of this investigation, it was decided that this route should be disregarded in favour of one of the alternatives.

Route (ii) may be considered more reliable for the purposes
of this study, though the approach is still a somewhat
indirect one. Bubble sizes and size distributions could
conceivably be measured by one of any number of local bubble
probes (54), and some hydrodynamic information on the grid
region might be obtained by the same technique. Certainly,
the effect of vessel internals on bubble size and velocity
could be quantified. Bubble interaction effects such as
coalescence and splitting could also yield to quantification
by techniques of this nature, though data interpretation is
likely to be difficult.

The use of local bubble probes would yield a fairly complete
matrix of level 2 information, but an estimation of the
interaction between phases would still be dependent on a
class C model. As discussed in Chapter 2, bubble coalescence
and splitting effects could seriously affect the applicability
of existing crossflow models, and in view of these
uncertainties, it was felt that this route should not form the
primary basis for the experimental investigation.

Route (iii), based on RTD information, represents a more
direct approach. It is limited to a lumped parameter or
class A description of the process, but does have the
advantage that the (level 3a) inferred MTC reflects real phase
interaction phenomena such as coalescence, splitting and grid
region effects. The lumped nature of this approach may be at

least partially overcome by experimentation at different bed
heights - in particular, the grid region may be accounted for
by simply allowing the model parameters to assume appropriate
values for a shallow bed. This entire procedure is, however,
strongly dependent on the assumptions on which the model is
based. It should also be pointed out that this approach is
insensitive to the assumption as to whether or not solids are
present in the lean phase, and data interpretation on the basis
of a simple solids-free bubble phase model is possible.

Route (iv), based on a reacting tracer, undoubtedly represents
the most direct approach. A conversion is measured, and no
modelling at all is called for. This is desirable *within* the
range of experimentation, but when scale-up extrapolations are
required such information is of little direct use. Scale-up
extrapolations are generally performed on the basis of a
hydrodynamic model. It is, however, possible to extract an
MTC from conversion data by working backwards. An MTC arrived
at in this way is subject to the same considerations as that
inferred from RTD information, though it should be noted that
the presence of solids within the bubbles could lead to biased
MTC's if the model assumes catalyst-free bubbles. The RTD
approach is essentially free of this complicating factor as
mentioned above.

Given the aim of developing and screening hydrodynamic models
for potential scale-up purposes, the RTD route (iii) is

potentially the most direct and trouble-free in the opinion of
the author. An ideal strategy might involve a combination of
routes, but in this investigation the use of the RTD route was
accepted as most suitable within the constraints on time and
capital.

3.2   Choice of Models

The sensitivity of the RTD model approach to the exact form
of the class A model dictates that several models, representing
a broad cross-section of possible assumptions, should be
employed. A model screening should be performed to isolate the
most realistic of these sets of assumptions, and the inter-
pretation of fluidised bed data should be based on this model.

The model screening in this study has two main components.
The first of these examines the situation in which all the gas
is fed via the grid, and in this case five models are considered.
Four of these are drawn from the literature, and the fifth is
considered novel. This screening will be referred to as the

general screening, and the five associated models as
general models.

The second screening component deals with split feed systems.
Two models, both considered novel, constitute the screening
basis. These will be referred to as sparger models, and the
two-model screening as the sparger screening.

3.2.1 General Models

3.2.1.1 May-Van Deemter Model

The May-Van Deemter or MVD model is selected because it reasonably
accounts for all the simple two-phase models appearing in the
literature. This model is shown in Figure 3.1.

3.2.1.2 Countercurrent Backmixing Model

The countercurrent backmixing or CCBM model is selected because
of its current popularity. As shown in Figure 3.2, it considers
the bed to be divided into three plug flow phases with solids
circulation and the possibility of gas downflow in the emulsion
phase. It should be noted that only the class A component of this
model is considered here.

3.2.1.3   Werther Film Diffusion Model

Werther's (98) film diffusion model, which will be referred

to as the WFD model, represents a somewhat novel approach in

that lateral diffusion in the cloud phase is presented as the

main phase interaction feature. This model employs three

phases as shown in Figure 3.3, with plug flow in the bubble

phase and axially stagnant cloud and emulsion phases.

3.2.1.4   Bubble-Phase Dispersion Model

The three models considered so far all assume plug flow in the

bubble phase. In the light of the discussion in section 2.2.3,

it would seem worthwhile to include a model which employs dispersed

plug flow in this phase. The bubble-phase dispersion or BPD model

is essentially an analogue of the MVD model, and is shown in

Figure 3.4.

3.2.1.5   Multiple Bubble-Track Model

In section 2.2.3 it is suggested that stages in series or dispersion

models for the bubble phase may not be appropriate for a freely

bubbling bed. Physically, the fact that large bubbles could over-

take small ones or bubble chains could overtake individually rising

bubbles suggests the formulation of a model with multiple plug flow

units in parallel for the bubble phase. It might be suggested that

such a formulation would represent a rather trivial variant of the

MVD model, so it would seem appropriate at this stage to explore the

incoming gas
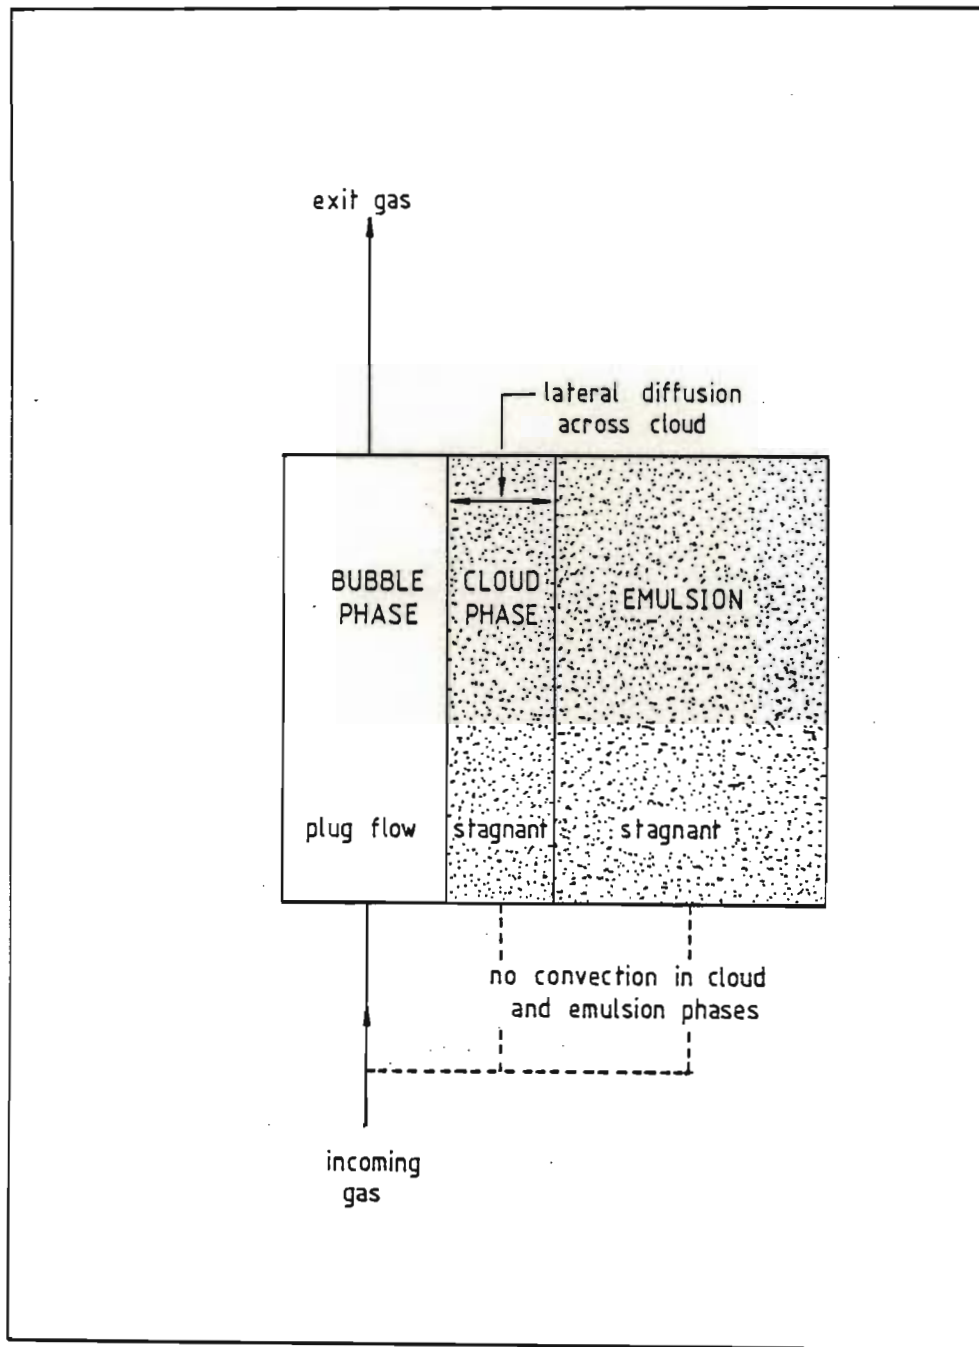

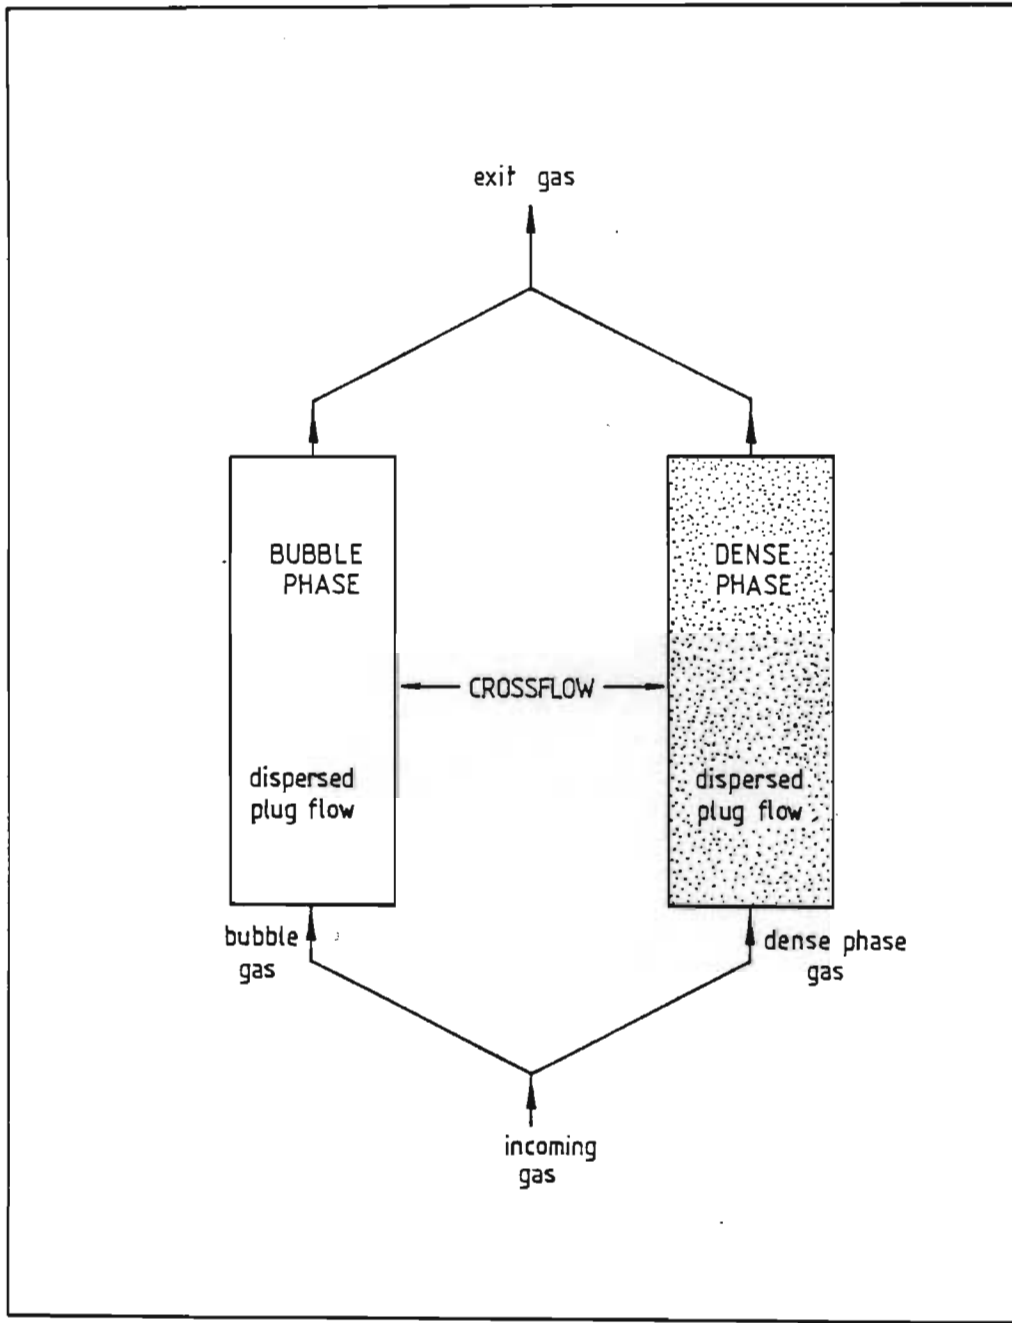

FIGURE 3.4   BPD   MODEL

possible advantages of such a model over its simpler counterpart.

As stated earlier, gross circulation cells and preferred bubble tracks are known (45, 53) to exist in fluidised beds: this situation is potentially better described by a multiple plug flow approach, since each plug flow unit could conceivably account for one preferred bubble path. This would introduce some degree of lateral variation into the simulation - something the MVD model is not capable of. A further point is that this model is able to describe a bimodal type of bubble velocity distribution, something which has been observed (51, 52) but which neither the MVD nor any of the other three models are capable of simulating.

As regards the potential application of this model to a slugging bed or a bubbling bed where a single probe is used as in this study, it is noted that although the argument based on lateral variation of bubble properties is no longer valid, the model still has merit in accounting for stochastic time variations in bubble (or slug) properties. The advantage of this model over the BPD model becomes less clear under these conditions, however, though it is by no means obvious that the multiple bubble-track approach is any less appropriate than those based on dispersed plug flow or mixed stages in series for the bubble phase.

A further possible criticism of this model is that it is of little practical use since the assumption of N tracks introduces an additional (N-1) degrees of freedom into the problem. It will be

shown, however, that the additional degrees of freedom may be accounted for independently and do not detract from its usefulness.

The multiple bubble-track or MBT model is shown in Figure 3.5 with an arbitrary number of five tracks - a discussion on the number of tracks used is deferred to section 4.1.5.

3.2.2   Sparger Models

When gas is introduced at some horizontal plane into an already fluidised system, how much catalyst does this gas "see" on its way through the bed?

It is relatively easy, in principle at least, to run cold model simulations with a split feed system. Residence time tests may be carried out by introducing an inert tracer into the sparger, and sampling the bed higher up. What is less obvious, however, is how to interpret such information.

An overall lumped parameter model is obviously no good, since the bed properties change abruptly with bed height at the level
FIGURE 3.5   MBT MODEL

of the sparger. Furthermore, it is not clear whether the bubbles
originating from the sparger should be regarded as a separate
bubble phase or not. If coalescence effects are strong it is
possible that most of these bubbles would join up with those
originating from the grid to effectively form a single lean phase.
If coalescence does not achieve significant lateral integration
(of the grid and sparger bubbles) a segregated model might be
more appropriate. For any real system the best description would
probably be found somewhere between these extremes.

Two models are put foward for the interpretation of sparger
RTD data. They correspond to the extreme cases of perfect lateral
mixing and complete lateral segregation of the bubble phase. A
model describing some intermediate case is not considered justified
at this stage. The form of the models is that of a two-phase model
with axial dispersion in the dense phase.

3.2.2.1   Laterally Mixed Bubble-Phase Model

The laterally mixed bubble-phase or LMBP model considers the bed
to be divided into two phases as shown in Figure 3.6. Gas flow
in the bubble phase is augmented by gas from the sparger at some
height L_s, and the bubble velocity and holdup change accordingly
from lumped values in the lower region to lumped values in the
upper. The interphase mass transfer coefficient is also considered
lumped in the lower and upper regions - RTD tests with tracer intro=
duced via the sparger are in fact aimed at measuring the MTC in the
upper region.
FIGURE 3.6   LMBP MODEL

3.2.2.2 Laterally Segregated Bubble-Phase Model

The laterally segregated bubble-phase or LSBP model is shown in Figure 3.7. Bubbles originating from the grid and from the sparger are considered to form separate bubble phases, and interaction between them is via the dense phase only. The MTC describing mass transfer between the grid bubbles and the dense phase is assumed to change abruptly from one constant value to another at the height of the sparger - this accounts for, in part at least, the axial dependence of the MTC.

It should be noted that the LMBP and LSBP models do not conform strictly to the definition of a class A model, since the parameters change at the height of the sparger. However, as far as the tests employed in this study are concerned, they are in fact class A : it is the lumped MTC in the region between the sparger and the bed surface that is inferred from RTD data.
FIGURE 3.7   LSBP MODEL

CHAPTER 4

SOFTWARE DEVELOPMENT FOR RTD INTERPRETATION

The experimental data and the model predictions may be
compared in either the time, Laplace or frequency domains.
Each approach has its merits, and the most suitable domain
for the problem at hand should be employed.

(i) Time Domain

The measured RTD data is used as is, and the model is solved
to yield a response in the time domain. The comparison is
direct, and a suitable measure of the degree of closure would
be:

$$\Phi = \int_{0}^{\infty} [Y(t) - \hat{Y}(t)]^2 dt \qquad (4.1)$$

where Φ is an objective function to be minimised, $Y(t)$ the
measured response and $\hat{Y}(t)$ the model response. This is a least
squares criterion for the estimation of model parameters.

(ii) Laplace Domain

The measured stimulus-response data is transformed by the (one-
sided) Laplace operator:

$$Y(s) = \int_{0}^{\infty} e^{-st} Y(t) \, dt \qquad (4.2)$$

where s is the Laplace variable. The model is solved in terms
of s rather than the time variable t, and comparison is carried

out in the Laplace domain. However, if a least squares

criterion is applied in the Laplace domain:

$$\Phi = \sum_s \left[Y(s) - \hat{Y}(s) \right]^2 \qquad (4.3)$$

it is not possible to estimate analytically the possible bias

in the model parameters (99). It may be shown (99) that least

squares in the time domain yields unbiased estimates - unfor=

tunately it is not known what criterion in the Laplace domain

is equivalent to least squares in the time domain.

(iii) Frequency Domain

The measured RTD data is re-cast to the form of a frequency

response on the basis of the Fourier transform operator:

$$Y(jw) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{\infty} e^{-jwt} Y(t)\, dt \qquad (4.4)$$

where j is the complex multiplier and w represents frequency.

The model is solved for frequency response, and is compared to

the measured data in this form.

In the case of RTD stimulus-response data the lower half of the

transform integral (from $-\infty$ to 0) falls away, since Y(t) is zero

for t<0. Ignoring the factor $\sqrt{2\pi}$, one may write:

$$Y(jw) = \int_0^{\infty} e^{-jwt} Y(t)\, dt \qquad (4.5)$$

It is immediately apparent that this represents a special
case of the Laplace transform operator, where the complex
variable s is replaced by an imaginary component jw.   In
this instance a criterion in the frequency domain equivalent
to least squares in the time domain does exist. Parseval's
equality

$$\int_0^\infty [f(t)]^2 \, dt \;\; = \;\; \frac{1}{\pi} \int_0^\infty |f(jw)|^2 \, dw \qquad\qquad (4.6)$$

applied to equation (4.1) leads to:

$$\Phi \;\; = \;\; \frac{1}{\pi} \int_0^\infty |Y(jw) - \hat{Y}(jw)|^2 \, dw \qquad\qquad (4.7)$$

which effectively calls for the minimisation of real and
imaginary deviations squared (99).

A scan of the literature and a cursory examination of the
mathematical form of the models considered in this study shows
that analytical solutions in the time domain are not feasible.
The models are, however, amenable to analytical solution in the
Laplace or frequency domains, and the latter is preferred due to
the existence of a suitable objective function for unbiased
parameter estimation as discussed above. The alternative is to
solve the models numerically in the time domain by some suitable
finite difference technique. This approach generally requires
a large amount of computing power - this does not appear to present
any significant obstacle at first glance. However, when it is

noted that the overall procedure involves <u>repeated</u> model
response evaluations for different parameter values, it
becomes clear that the cost in terms of computer time could
become excessive - this was indeed found to be the case in
the early stages of this investigation. It was decided that
analytical frequency response expressions should be employed
wherever possible.

The rest of this chapter is divided into three sections.
The first of these deals with the formulation and analytical
solution (in the frequency domain) of the five general models
discussed in Chapter 3. The second describes the formulation
and solution of the two (specialised) sparger models, and in the
third section the overall data processing and information flow
strategy is set out.

4.1 General Model Formulation and Analytical Solution

4.1.1 MVD Model

The May-Van Deemter or MVD model has been solved in the open
literature (15) for $U_d = 0$. The solution presented here follows
a similar pattern, with the restriction on U_d removed.

The model formulation proceeds as follows: a dynamic material
balance over an incremental height Δz of the bubble phase leads to

$$\left[\text{accumulation} \right] = \left[\begin{array}{l} \text{flow in -} \\ \text{flow out by} \\ \text{convection} \end{array} \right] + \left[\begin{array}{l} \text{net gain} \\ \text{by interphase} \\ \text{transfer} \end{array} \right]$$

In mathematical symbols:

$$\delta \, A_t \, \Delta z \, \frac{\partial C_b}{\partial t} \;=\; \delta \, A_t \, U_b \, [C_{b|z} - C_{b|z+\Delta z}]$$

$$- (K_{be})_b \, \delta \, A_t \, \Delta z \, [C_b - C_e] \qquad (4.8)$$

Dividing through by $\delta \, A_t \, \Delta z$ and taking the limit as $\Delta z \to 0$:

$$\frac{\partial C_b}{\partial t} + U_b \frac{\partial C_b}{\partial z} + (K_{be})_b \, [C_b - C_e] \;=\; 0 \qquad (4.7)$$

Define dimensionless time $\theta = t(U_b/L_f)$

and dimensionless distance $\xi = z/L_f$

and substitute:

$$\frac{\partial C_b}{\partial \theta} + \frac{\partial C_b}{\partial \xi} + X_b [C_b - C_e] \;=\; 0 \qquad (4.10)$$

where $X_b = (K_{be})_b \, L_f/U_b$ is defined as the crossflow ratio.

For the dense phase:

$$\begin{bmatrix} \text{accumulation} \end{bmatrix} = \begin{bmatrix} \text{in-out by} \\ \text{convention} \end{bmatrix} + \begin{bmatrix} \text{in-out by} \\ \text{interphase} \\ \text{transfer} \end{bmatrix} + \begin{bmatrix} \text{in-out by} \\ \text{axial} \\ \text{dispersion} \end{bmatrix}$$

or $\quad (1-\delta)\varepsilon_d \, A_t \, \Delta z \, \dfrac{\partial C_e}{\partial t} \;=\; (1-\delta) \, U_d \, A_t \, [C_{e|z} - C_{e|z+\Delta z}]$

$$+ (K_{be})_b \, \delta \, A_t \, \Delta z \, [C_b - C_e]$$

$$- D_d \, (1-\delta) \, A_t \, \varepsilon_d \, [\frac{\partial C_e}{\partial z}\big|_z - \frac{\partial C_e}{\partial z}\big|_{z+\Delta z}] \qquad (4.11)$$

Dividing through by $(1-\delta) \, \epsilon_d \, A_t \, \Delta z$ and taking the limit as $\Delta z \to 0$:

$$\frac{\partial C_e}{\partial t} + \left(\frac{U_d}{\epsilon_d}\right) \frac{\partial C_e}{\partial z} - \frac{\delta (K_{be}) b}{(1-\delta)\epsilon_d} \left[C_b - C_e\right] - D_d \frac{\partial^2 C_e}{\partial z^2} = 0 \qquad (4.12)$$

Introducing the dimensionless variables θ and ξ:

$$\frac{\partial C_e}{\partial \theta} + \left(\frac{U_d}{\epsilon_d U_b}\right) \frac{\partial C_e}{\partial \xi} - \frac{\delta X_b}{(1-\delta)\epsilon_d} \left[C_b - C_e\right] - N_d \frac{\partial^2 C_e}{\partial \xi^2} = 0 \qquad (4.13)$$

where $N_d = D_d/(U_b L_f)$ is the number of dense phase dispersion units.

The initial condition or I.C. is:

$$C_b(\xi,0) = C_e(\xi,0) = 0 \qquad (4.14)$$

and the boundary conditions or B.C.'s:

$$\text{(i)} \quad C_b(0,\theta) = C_0 \qquad (4.15)$$

$$\text{(ii)} \quad \left.\frac{\partial C_e}{\partial \xi}\right|_{\xi=0} = 0 \qquad (4.16)$$

$$\text{(iii)} \quad \left.\frac{\partial C_e}{\partial \xi}\right|_{\xi=1} = 0 \qquad (4.17)$$

These B.C.'s are in fact those used by Van Deemter (15), and the suitability or otherwise of the last two is a matter for debate. This question will not be ventured into at this stage, however, since it is the generally accepted form of the model that is required for the purpose of comparison with other models.

The reader's attention is drawn to the fact that, in the
ensuing sections, the Laplace transform is used rather than
the Fourier transform. It is understood that, for the
conditions encountered in this study, the Laplace variable s
may be replaced by the frequency variable jw at any stage.

The solution for frequency response proceeds as follows:
equations (4.10) and (4.13) are transformed, with the I.C.'s
zero in both phases, to yield

$$\frac{dC_b}{d\xi} + (X_b+s)\ C_b = X_b C_e \tag{4.18}$$

and

$$N_d \frac{d^2C_e}{d\xi^2} - \left(\frac{U_d}{\varepsilon_d U_b}\right) \frac{dC_e}{d\xi} - \left(\frac{\delta X_b}{(1-\delta)\varepsilon_d} + s\right) C_e = \left(\frac{\delta X_b}{(1-\delta)\varepsilon_d}\right) C_b \tag{4.19}$$

Now C_e is written in terms of C_b from equation (4.18) and the
resulting expression is substituted into (4.19). The result is:

$$\frac{d^3C_b}{d\xi^3} + \left[X_b+s - \frac{U_d}{\varepsilon_d U_b} \frac{1}{N_d}\right] \frac{d^2C_b}{d\xi^2} - \left[\frac{U_d(X_b+s)}{\varepsilon_d U_b N_d} + \left(\frac{\delta X_b}{(1-\delta)\varepsilon_d} + s\right) \frac{1}{N_d}\right] \frac{dC_b}{d\xi}$$

$$+ \left[\frac{\delta X_b^2}{(1-\delta)\varepsilon_d N_d} - \left(\frac{\delta X_b}{(1-\delta)\varepsilon_d} + s\right) \frac{X_b+s}{N_d}\right] C_b = 0 \tag{4.20}$$

The transformed boundary conditions are:

$$C_b(\xi = 0, s) = 1 \tag{4.21}$$

(since C_0 is taken to be a Dirac delta function)

$$\frac{dC_e}{d\xi}\bigg|_{\xi=0} = 0 \tag{4.22}$$

$$\frac{dC_e}{d\xi}\bigg|_{\xi=1} = 0 \tag{4.23}$$

Now assume that equation (4.20) has a solution of the form:

$$C_b(\xi,s) = A_1 e^{\lambda_1 \xi} + A_2 e^{\lambda_2 \xi} + A_3 e^{\lambda_3 \xi} \tag{4.24}$$

where the A_i are constants to be determined, and λ_i the roots of:

$$\lambda^3 + \left[X_b + s + \frac{U_d}{\epsilon_d U_b N_d}\right]\lambda^2 + \left[\frac{U_d(X_b+s)}{\epsilon_d U_b N_d} + \left(\frac{\delta X_b}{(1-\delta)\epsilon_d} + s\right)\frac{1}{N_D}\right]\lambda$$

$$+ \left[\frac{\delta X_b^2}{(1-\delta)\epsilon_d N_d} - \left(\frac{\delta X_b}{(1-\delta)\epsilon_d} + s\right)\frac{X_b+s}{N_d}\right] = 0 \tag{4.25}$$

B.C. (4.21) gives:

$$C_b(0,s) = A_1 + A_2 + A_3 = 1 \tag{4.26}$$

or $\quad A_3 = 1 - A_1 - A_2 \tag{4.27}$

Now, from (4.18):

$$\frac{dC_e}{d\xi} = \frac{1}{X_b}\frac{d^2C_b}{d\xi^2} + \frac{X_b+s}{X_b}\frac{dC_b}{d\xi} \tag{4.28}$$

In terms of (4.24) this becomes:

$$\frac{dC_e}{d\xi} = \frac{1}{X_b}\left[A_1(\lambda_1^2 e^{\lambda_1 \xi} - \lambda_3^2 e^{\lambda_3 \xi}) + A_2(\lambda_2^2 e^{\lambda_2 \xi} - \lambda_3^2 e^{\lambda_3 \xi})\right.$$

$$\left. + \lambda_3^2 e^{\lambda_3 \xi}\right] + \frac{X_b+s}{X_b}\left[A_1(\lambda_1 e^{\lambda_1 \xi} - \lambda_3 e^{\lambda_3 \xi})\right.$$

$$\left. + A_2(\lambda_2 e^{\lambda_2 \xi} - \lambda_3 e^{\lambda_3 \xi}) - \lambda_3 e^{\lambda_3 \xi}\right] \tag{4.29}$$

Setting this expression equal to zero at $\xi = 0$ and $\xi = 1$ and

eliminating A_1 leads to:

$$A_2 = \frac{(e^{\lambda_3} - e^{\lambda_1})/\gamma_2}{(e^{\lambda_1} - e^{\lambda_2})/\gamma_3 + (e^{\lambda_3} - e^{\lambda_1})/\gamma_2 + (e^{\lambda_2} - e^{\lambda_3})/\gamma_1} \qquad (4.30)$$

where $\gamma_i = \lambda_i^2 + (X_b + s)\,\lambda_i$. $\qquad (4.31)$

For ease of manipulation define

$$\beta_i = (e^{\lambda l} - e^{\lambda k})/\gamma_i \qquad (4.32)$$

where $l = 3$, $k = 1$ for $i = 2$

$l = 2$ $k = 3$ for $i = 1$

$l = 1$ $k = 2$ for $i = 3$

In terms of β_i's, A_2 becomes

$$A_2 = \frac{\beta_2}{\beta_1 + \beta_2 + \beta_3} \qquad (4.33)$$

Solving for A_1 and A_3 leads to:

$$A_1 = \frac{\beta_1}{\beta_1 + \beta_2 + \beta_3} \qquad (4.34)$$

and $A_3 = \dfrac{\beta_3}{\beta_1 + \beta_2 + \beta_3}$ $\qquad (4.35)$

The Laplace domain solution for C_b is therefore

$$C_b(\xi,s) = \frac{\beta_1 e^{\lambda_1 \xi} + \beta_2 e^{\lambda_2 \xi} + \beta_3 e^{\lambda_3 \xi}}{\beta_1 + \beta_2 + \beta_3} \qquad (4.36)$$

with:

$$\beta_1 \;=\; \frac{1}{\lambda_1}\,\frac{e^{\lambda_2}-e^{\lambda_3}}{\lambda_1+X_b+s} \tag{4.37}$$

$$\beta_2 \;=\; \frac{1}{\lambda_2}\,\frac{e^{\lambda_3}-e^{\lambda_1}}{\lambda_2+X_b+s} \tag{4.38}$$

$$\beta_3 \;=\; \frac{1}{\lambda_3}\,\frac{e^{\lambda_1}-e^{\lambda_2}}{\lambda_3+X_b+s} \tag{4.39}$$

The solution for C_e is obtained by substituting (4.36) into (4.18).
The result is:

$$C_e(\xi,s) \;=\; \frac{1}{X_b(\beta_1+\beta_2+\beta_3)}\,\Big[\beta_1 e^{\lambda_1\xi}(\lambda_1+X_b+s) \;+$$

$$\beta_2 e^{\lambda_2\xi}\,(\lambda_2+X_b+s) \;+\; \beta_3 e^{\lambda_3\xi}(\lambda_3+X_b+s)\Big] \tag{4.40}$$

Now the concentration measured by an aspirating probe in the bed
is given by:

$$\bar{C} \;=\; (\delta\,C_b + (1-\delta)\varepsilon_d\,C_e)/(\delta + (1-\delta)\varepsilon_d) \tag{4.41}$$

and equations (4.36) and (4.40) are combined accordingly.

This solution, programmed in FORTRAN V, is evaluated on a Univac
1160 computer. A listing is given in Appendix B. The roots of
the complex third-order polynomial (equation 4.25) are determined
numerically by the Univac library routine ROOTCP.

4.1.2 CCBM Model

To the best of the author's knowledge, no dynamic solution for
this model has been published previously. The solution presented
here is for a boundary condition at the top of the bed which
is somewhat different to that normally employed; the nature
of the model in the dynamic mode necessitates this modification.

A dynamic material balance on the bubble phase yields:

$$
\begin{bmatrix} \text{accm} \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convection} \end{bmatrix} + \begin{bmatrix} \text{net gain by} \\ \text{interphase} \\ \text{transfer} \end{bmatrix}
$$

or $\quad \delta A_t \Delta z \, \dfrac{\partial C_b}{\partial t} = \delta A_t U_b \left[C_b|_z - C_b|_{z+\Delta z} \right] - (K_{bc})_b \, \delta A_t \Delta z \left[C_b - C_c \right]$ $\quad$ (4.42)

Dividing by $\delta A_t \Delta z$ and taking the limit on Δz:

$$
\frac{\partial C_b}{\partial t} + U_b \frac{\partial C_b}{\partial z} + (K_{bc})_b \left[C_b - C_c \right] = 0 \qquad\qquad (4.43)
$$

and introducing dimensionless time and distance variables:

$$
\frac{\partial C_b}{\partial \theta} + \frac{\partial C_b}{\partial \xi} + X_{bc} \left[C_b - C_c \right] = 0 \qquad\qquad (4.44)
$$

A similar treatment on the cloud phase leads to:

$$
\begin{bmatrix} \text{accm} \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convention} \end{bmatrix} + \begin{bmatrix} \text{net gain by} \\ \text{bbl-cloud} \\ \text{transfer} \end{bmatrix} + \begin{bmatrix} \text{net gain by} \\ \text{cloud-emulsion} \\ \text{transfer} \end{bmatrix}
$$

If α is the volume ratio of this phase to the bubble phase, then:

$$\alpha \; \delta \; \varepsilon_d \; A_t \Delta z \; \frac{\partial C_c}{\partial t} \; = \; A_t \; \alpha \; \delta \; \varepsilon_d \; U_b \; \left[C_c \Big|_z - C_c \Big|_{z+\Delta z} \right]$$

$$+ \; (K_{bc})_b \; \delta \; A_t \; \Delta z \; [C_b - C_c] - (K_{ce})_b \; \delta \; A_t \; \Delta z \; [C_c - C_e] \quad (4.45)$$

Dividing by $\alpha \; \delta \; \varepsilon_d \; A_t \; \Delta z$ and letting $\Delta z \rightarrow 0$:

$$\frac{\partial C_c}{\partial t} + U_b \; \frac{\partial C_c}{\partial z} + \frac{(K_{bc})_b + (K_{ce})_b}{\alpha \varepsilon_d} \; C_c \; = \; \frac{(K_{bc})_b}{\alpha \varepsilon_d} \; C_b + \frac{(K_{ce})_b}{\alpha \varepsilon_d} \; C_e \quad (4.46)$$

or, in terms of θ and ξ:

$$\frac{\partial C_c}{\partial \theta} + \frac{\partial C_c}{\partial \xi} + \frac{(X_{bc} + X_{ce})}{\alpha \varepsilon_d} \; C_c \; = \; (\frac{X_{bc}}{\alpha \varepsilon_d}) \; C_b + (\frac{X_{ce}}{\alpha \varepsilon_d}) \; C_e \quad (4.47)$$

A mass balance on the emulsion gives:

$$\begin{bmatrix} accm \end{bmatrix} \; = \; \begin{bmatrix} in\text{-}out \\ convection \end{bmatrix} \; + \; \begin{bmatrix} net \; gain \; by \\ interphase \\ transfer \end{bmatrix}$$

i.e. $(1-\delta-\alpha\delta)\varepsilon_d \; A_t \; \Delta z \; \dfrac{\partial C_e}{\partial t} \; = \; (1-\delta-\alpha\delta) \; \varepsilon_d \; U_e \; A_t \; \left[C_e \Big|_z - C_e \Big|_{z+\Delta z} \right]$

$$+ \; (K_{ce})_b \; \delta \; A_t \; \Delta z \; [C_c - C_e] \quad (4.48)$$

Dividing by $(1-\delta-\alpha\delta) \; \varepsilon_d \; A_t \; \Delta z$ and taking the limit:

$$\frac{\partial C_e}{\partial t} + U_e \; \frac{\partial C_e}{\partial z} - \frac{(K_{ce})_b}{(1-\delta-\alpha\delta)\varepsilon_d} \; [C_c - C_e] \; = \; 0 \quad (4.49)$$

and in terms of the dimensionless variables:

$$\frac{\partial C_e}{\delta \theta} + (\frac{U_e}{U_b}) \; \frac{\partial C_e}{\partial \xi} - \frac{\delta X_{ce}}{(1-\delta-\alpha\delta)\varepsilon_d} \; [C_c - C_e] \; = \; 0 \quad (4.50)$$

The associated I.C.'s are:

$$C_b(\xi,0) \; = \; C_c(\xi,0) \; = \; C_e(\xi,0) \; = \; 0 \tag{4.51}$$

and two of the B.C.'s

$$C_b(0,\theta) \; = \; C_0 \tag{4.52}$$

$$C_c(0,\theta) \; = \; \frac{(U_0-\delta U_b) \; C_0 \; - \; (1-\delta-\alpha\delta)\epsilon_d \; U_e \; C_e(0,\theta)}{\alpha \; \delta \; \epsilon_d \; U_b} \tag{4.53}$$

The third boundary condition is usually specified as:

$$C_c(L_f,\theta) \; = \; C_e(L_f,\theta) \tag{4.54}$$

Several attempts at a solution for this model with B.C. (4.54) were made. Bivariate Laplace transform and transition matrix techniques were employed, and in both cases solutions which appeared perfectly normal on paper were obtained. However, when these solutions were programmed and run on the computer, nonsensical results were obtained for negative (i.e. downflowing) emulsion velocities. The cause was traced to the emergence of a complex root with a positive real component. The magnitude of this component was such that numbers of the order of 10^{26} were added to numbers of the order of unity, the result being a complete loss of numerical significance. In order to suppress this pole in the right-hand half-plane, it was deemed necessary to replace the boundary condition given by equation (4.54) by the condition that all concentrations remain finite as bed height tends to infinity, i.e.

$$\lim_{\xi \to \infty} C_b(\xi,\theta), \ C_c(\xi,\theta), \ C_e(\xi,\theta) \ < \ \infty \qquad (4.55)$$

Applying the Laplace transform with respect to time, using the I.C. given by (4.51) gives, for equation (4.44):

$$\frac{dC_b}{d\xi} + (X_{bc} + s) \ C_b \ = \ X_{bc} \ C_c \qquad (4.56)$$

For equation (4.47)

$$\frac{dC_c}{d\xi} + \left[\frac{X_{bc} + X_{ce}}{\alpha\varepsilon_d} + s\right] C_c \ = \ \left[\frac{X_{bc}}{\alpha\varepsilon_d}\right] C_b + \left[\frac{X_{ce}}{\alpha\varepsilon_d}\right] C_e \qquad (4.57)$$

and for (4.50)

$$\frac{dC_e}{d\xi} + \left(\frac{U_b}{U_e}\right) \left[\frac{\delta X_{ce}}{(1-\delta-\alpha\delta)\varepsilon_d} + s\right] C_e \ = \ \left(\frac{U_b}{U_e}\right) \left[\frac{\delta X_{ce}}{(1-\delta-\alpha\delta)\varepsilon_d}\right] C_c \qquad (4.58)$$

For ease of manipulation define

$$a_1 \ = \ X_{bc} + s \qquad (4.59)$$

$$a_2 \ = \ (X_{bc} + X_{ce})/\alpha\varepsilon_d + s \qquad (4.60)$$

$$a_3 \ = \ (U_b/U_e) \ [\delta X_{ce}/((1-\delta-\alpha\delta)\varepsilon_d) + s] \qquad (4.61)$$

$$a_4 \ = \ X_{bc}/(\alpha\varepsilon_d) \qquad (4.62)$$

$$a_5 \ = \ X_{ce}/(\alpha\varepsilon_d) \qquad (4.63)$$

$$a_6 \ = \ (U_b/U_e) \ [\delta X_{ce}/((1-\delta-\alpha\delta)\varepsilon_d)] \qquad (4.64)$$

Equations (4.56) to (4.58) then become:

$$\frac{dC_b}{d\xi} + a_1 C_b \ = \ X_{bc} \ C_c \qquad (4.65)$$

$$\frac{dC_c}{d\xi} + a_2 C_c = a_4 C_b + a_5 C_e \qquad (4.66)$$

$$\frac{dC_e}{d\xi} + a_3 C_e = a_6 C_c \qquad (4.67)$$

Transforming these equations for a second time, this time with respect to ξ, and letting the transformed distance variable be υ:

$$C_b \upsilon - C_b(\xi=0,s) + a_1 C_b = X_{bc} C_c \qquad (4.68)$$

$$C_c \upsilon - C_c(\xi=0,s) + a_2 C_c = a_4 C_b + a_s C_e \qquad (4.69)$$

$$C_e \upsilon - C_e(\xi=0,s) + a_3 C_e = a_6 C_c \qquad (4.70)$$

The boundary condition given by (4.52), in its tranformed state and for C_0 a delta function, gives

$$C_b(\xi=0,s) = 1 \qquad (4.71)$$

The B.C. given by (4.53) then gives

$$C_c(\xi=0,s) = X_1 - X_2 C_e(\xi=0,s) \qquad (4.72)$$

where $X_1 = (U_0 - \delta U_b)/(\alpha \delta \varepsilon_d U_b) \qquad (4.73)$

and $X_2 = (1-\delta-\alpha\delta) U_e \varepsilon_d/(\alpha \delta \varepsilon_d U_b) \qquad (4.74)$

Substituting from (4.71) and (4.72) and writing equations (4.68) to (4.70) in matrix form:

$$
\begin{bmatrix}
\nu+a_1 & -X_{bc} & 0 \\
-a_4 & \nu+a_2 & -a_5 \\
0 & -a_6 & \nu+a_3
\end{bmatrix}
\begin{bmatrix}
C_b \\
C_c \\
C_e
\end{bmatrix}
=
\begin{bmatrix}
1 \\
X_1-X_2C_{eo} \\
C_{eo}
\end{bmatrix}
\qquad (4.75)
$$

where $C_e(\xi=0,s)$ is abbreviated C_{eo}. Now the exponential factors in ξ are specified by the roots of the 3x3 determinant:

$$
\begin{aligned}
\Delta \;=\; & \nu^3 + (a_1+a_2+a_3)\nu^2 + (a_2a_3-a_5a_6+a_1a_2+a_1a_3-a_4X_{bc})\nu \\
& + a_1(a_2a_3-a_5a_6) - a_3a_4X_{bc}
\end{aligned}
\qquad (4.76)
$$

Define a_7, a_8 and a_9 such that

$$
\Delta \;=\; \nu^3+a_7\nu^2+a_8\nu+a_9 \qquad (4.77)
$$

For negative or downward emulsion velocities this expression has two roots with negative real components and one with a positive real component. To satisfy B.C. (4.55) this pole must be constrained to coincide with a zero on the complex plane.

From equation (4.75):

$$
\begin{aligned}
C_b \;=\; & \frac{1}{\Delta}\{[(\nu+a_2)(\nu+a_3) - a_5a_6]+ (X_1-X_2C_{eo}) [X_{bc}(\nu+a_3)] \\
& + C_{eo} [a_5X_{bc}]\}
\end{aligned}
\qquad (4.78)
$$

by Cramer's Rule, and this may be re-written as:

$$C_b = \frac{1}{\Delta}\left[\nu^2 + (a_2+a_3+X_{bc}X_1-X_{bc}X_2C_{eo})\nu\right.$$

$$\left. + (a_2a_3-a_5a_6+X_{bc}a_3X_1+a_5X_{bc}C_{eo}-X_2X_{bc}a_3C_{eo})\right] \qquad (4.79)$$

If the roots of (4.77) are given by λ_i, where λ_3 has a positive real component, then the numerator of (4.79) must equal $(\nu-\lambda_3)(\nu-\gamma_1)$ where γ_1 is some constant. Equating the numerators:

$$\nu^2 - (\lambda_3+\gamma_1)\nu + \lambda_3\gamma_1 = \nu^2 + (a_2+a_3+X_{bc}X_1-X_{bc}X_2C_{eo})\nu$$

$$+ a_2a_3 - a_5a_6 + X_{bc}a_3X_1 - (a_5X_{bc}-X_2X_{bc}a_3)C_{eo} \qquad (4.80)$$

Comparing coefficients:

$$(a_2+a_3+X_{bc}X_1) - (X_{bc}X_2)C_{eo} = -(\lambda_3+\gamma_1) \qquad (4.81)$$

$$(a_2a_3-a_5a_6+X_{bc}a_3X_1) + (a_5X_{bc}-X_2X_{bc}a_3)C_{eo} = \lambda_3\gamma_1 \qquad (4.82)$$

Define a_{10} through a_{13} such that

$$a_{10} + a_{11}C_{eo} = -(\lambda_3+\gamma_1) \qquad (4.83)$$

$$a_{12} + a_{13}C_{eo} = \lambda_3\gamma_1$$

and solving this sytem for C_{eo} yields:

$$C_{eo} = -\frac{\lambda_3^2 + \lambda_3 a_{10}+a_{12}}{\lambda_3 a_{11}+a_{13}} \qquad (4.85)$$

and $\gamma_1 = (a_{12}+a_{13}C_{eo})/\lambda_3$ $\qquad$ (4.86)

Now $C_b(\nu,s) = \dfrac{\nu-\gamma_1}{(\nu-\lambda_1)(\nu-\lambda_2)}$ $\qquad$ (4.87)

Splitting into partial fractions and inverse transforming with respect to ν:

$$C_b(\xi,s) = (\dfrac{\lambda_1-\gamma_1}{\lambda_1-\lambda_2})e^{\lambda_1\xi} + (\dfrac{\lambda_2-\gamma_1}{\lambda_2-\lambda_1})e^{\lambda_2\xi} \qquad (4.88)$$

For the cloud phase, Cramer's Rule applied to (4.75) gives:

$$C_c = \dfrac{C_{co}}{\Delta}\{\nu^2 + [a_1+a_3 + \dfrac{a_5C_{eo}+a_4}{C_{co}}]\nu$$
$$ + [a_1a_3 + \dfrac{a_1a_5C_{eo}+a_3a_4}{C_{co}}]\} \qquad (4.89)$$

where $C_{co} = X_1 - X_2 C_{eo}$. As before, the numerator must equal $C_{co}(\nu-\lambda_3)(\nu-\gamma_2)$, so

$$a_1 + a_3 + \dfrac{a_5C_{eo}+a_4}{C_{co}} = -(\lambda_3+\gamma_2) \qquad (4.90)$$

and $a_1a_3 + \dfrac{a_1a_5C_{eo}+a_3a_4}{C_{co}} = \lambda_3\gamma_2$ $\qquad$ (4.91)

Therefore $\gamma_2 = \dfrac{1}{\lambda_3}[a_1a_3 + \dfrac{a_1a_5C_{eo}+a_3a_4}{C_{co}}]$ $\qquad$ (4.92)

or $\gamma_2 = -\lambda_3 - [a_1+a_3 + \dfrac{a_5C_{eo}+a_4}{C_{co}}]$ $\qquad$ (4.93)

Equations (4.92) and (4.93) in fact yield identical values for γ_2, and $C_c(\xi,s)$ becomes

$$C_c(\xi,s) = C_{co}\left[\left(\frac{\lambda_1-\gamma_2}{\lambda_1-\lambda_2}\right)e^{\lambda_1\xi} + \left(\frac{\lambda_2-\gamma_2}{\lambda_2-\lambda_1}\right)e^{\lambda_2\xi}\right] \tag{4.94}$$

Cramer's Rule applied to (4.75) for the emulsion phase leads to:

$$C_e = \frac{C_{eo}}{\Delta}\left\{\nu^2 \left[a_1+a_2+a_6\frac{C_{co}}{C_{eo}}\right]\nu\right.$$
$$\left. + \left[a_1a_2-a_4X_{bc} + \frac{a_1a_6C_{co}+a_4a_6}{C_{eo}}\right]\right\} \tag{4.95}$$

The numerator must contain a $(\nu-\lambda_3)$ term, so setting it equal to $C_{eo}(\nu-\lambda_3)(\nu-\gamma_3)$ and equating coefficients:

$$a_1 + a_2 + a_6\frac{C_{co}}{C_{eo}} = -(\lambda_3+\gamma_3) \tag{4.96}$$

$$a_1a_2 - a_4X_{bc} + \frac{a_1a_6C_{eo}+a_4a_6}{C_{eo}} = \lambda_3\phi_3 \tag{4.97}$$

and
$$\gamma_3 = \frac{1}{\lambda_3}\left[a_1a_2-a_4X_{bc} + \frac{a_1a_6C_{co}+a_4a_6}{C_{eo}}\right] \tag{4.98}$$

or
$$\gamma_3 = -\lambda_3 - \left[a_1+a_2+a_6\frac{C_{co}}{C_{eo}}\right] \tag{4.99}$$

Once again, these expressions yield identical values for γ_3 and $C_e(\xi,s)$ may be obtained by inverse transformation:

$$C_e = C_{eo}\left[\left(\frac{\lambda_1-\gamma_3}{\lambda_1-\lambda_2}\right)e^{\lambda_1\xi} + \left(\frac{\lambda_2-\gamma_3}{\lambda_2-\lambda_1}\right)e^{\lambda_2\xi}\right] \tag{4.100}$$

For an aspirating probe in the bed:

$$\bar{C} = \frac{\delta C_b + \alpha\delta\varepsilon_d C_c + (1-\delta-\alpha\delta)\varepsilon_d C_e}{\delta + \alpha\delta\varepsilon_d + (1-\delta-\alpha\delta)\varepsilon_d} \tag{4.101}$$

and the solutions for C_b, C_c and C_e are combined accordingly to yield an overall frequency response. A FORTRAN V listing of the solution is given in Appendix B.

4.1.3 WFD Model

As far as the author is aware, no dynamic-mode solution to the Werther film diffusion or WFD model has been published. Werther (98) has solved this model for a reacting tracer under steady-state conditions, but does not appear to have considered an unsteady-state application as yet.

The WFD model employs axially stagnant cloud and emulsion phases. The bubble and emulsion phases are laterally well mixed, and the cloud phase offers (lateral) diffusional resistance to tracer migration. The diffusion law is defined as:

$$\frac{dN}{dt} = -D_f \, a_b \, V_b \, \frac{\partial C_c}{\partial x} \tag{4.102}$$

where $\frac{dN}{dt}$ is the rate of transfer of the species under consideration, D_f the diffusion coefficient and $\frac{\partial C_c}{\partial x}$ the lateral concentration gradient in the cloud. The volume of the bubble phase is represented by V_b, and a_b is the bubble-cloud interfacial area per unit bubble volume. If the overall cloud thickness is γ_c and the cloud is reasonably thin, one can reasonably assume

$$(K_{be})_b = (\frac{D_f \, a_b}{\gamma_c}) \tag{4.103}$$

In addition, the ratio of cloud to bubble volume α may be written:

$$\alpha = a_b \gamma_c \qquad (4.104)$$

This model may thus be formulated in terms of a conventional mass transfer coefficient, even though a different transfer mechanism is put forward.

A mass balance on the bubble phase yields:

$$\left[\text{accm} \right] = \left[\begin{array}{c} \text{in-out} \\ \text{convection} \end{array} \right] + \left[\begin{array}{c} \text{gain by} \\ \text{interphase} \\ \text{transfer} \end{array} \right]$$

$$\delta A_t \Delta z \frac{\partial C_b}{\partial t} = \delta A_t U_b \left[C_b \big|_z - C_b \big|_{z+\Delta z} \right]$$

$$+ D_f a_b \delta A_t \Delta z \frac{\partial C_c}{\partial x}\big|_{x=0} \qquad (4.105)$$

Dividing by $\delta A_t \Delta z$ and letting $\Delta z \to 0$:

$$\frac{\partial C_b}{\partial t} + U_b \frac{\partial C_b}{\partial z} - D_f a_b \frac{\partial C_c}{\partial x}\big|_{x=0} = 0 \qquad (4.106)$$

Introducing θ, ξ and $\zeta = x/\gamma_c$:

$$\frac{\partial C_b}{\partial \theta} + \frac{\partial C_b}{\partial \xi} - \left(\frac{D_f a_b L_f}{U_b \gamma_c} \right) \frac{\partial C_c}{\partial \zeta}\big|_{\zeta=0} \qquad (4.107)$$

or, in terms of a mass transfer coefficient

$$\frac{\partial C_b}{\partial \theta} + \frac{\partial C_b}{\partial \xi} - X_b \frac{\partial C_c}{\partial \zeta}\big|_{\zeta=0} = 0 \qquad (4.108)$$

A mass balance on the cloud phase:

$$
\left[\text{accm} \right] \quad = \quad \left[\begin{array}{l} \text{in-out by} \\ \text{lateral diffusion} \end{array} \right]
$$

so $\quad \delta A_t \, \Delta z \, a_b \, \Delta x \, \varepsilon_d \, \dfrac{\partial C_c}{\partial t} = D_f a_b \, A_t \, \Delta z \, \delta \Big[\dfrac{\partial C_c}{\partial x} \Big|_x \quad \dfrac{\partial C_c}{\partial x} \Big|_{x+\Delta x} \Big]$ $\qquad$ (4.109)

dividing through by $\delta A_t \, \Delta z \, a_b \, \Delta x \, \varepsilon_d$ and letting Δx tend to zero:

$$
\frac{\partial C_c}{\partial t} - \frac{D_f}{\varepsilon_d} \frac{\partial^2 C_c}{\partial x^2} = 0 \qquad\qquad (4.110)
$$

Introducing dimensionless variables and substituting from (4.103) and (4.104):

$$
\frac{\partial C_c}{\partial \theta} - \frac{X_b}{\alpha \varepsilon_d} \frac{\partial^2 C_c}{\partial \zeta^2} = 0 \qquad\qquad (4.111)
$$

A material balance on the emulsion gives:

$$
\left[\text{accm} \right] \quad = \quad \left[\begin{array}{l} \text{in-out by} \\ \text{lateral diffusion} \end{array} \right]
$$

or $\quad A_t \, \Delta z \, (1-\delta-\alpha\delta) \varepsilon_d \, \dfrac{\partial C_e}{\partial t} = D_f a_b \, A_t \, \Delta z \, \delta \, \dfrac{\partial C_c}{\partial x} \Big|_{x=\gamma_c}$ $\qquad$ (4.112)

Dividing by $A_t \, \Delta z \, (1-\delta-\alpha\delta)\varepsilon_d$ and introducing θ and ζ:

$$
\frac{\partial C_e}{\partial \theta} + \frac{\delta \, X_b}{(1-\delta-\alpha\delta)\varepsilon_d} \frac{\partial C_c}{\partial \zeta} \Big|_{\zeta=1} \qquad\qquad (4.113)
$$

The initial conditions are:

$$C_b(\zeta,0) \;=\; C_c(\xi,\zeta,0) \;=\; C_e(\xi,0) \;=\; 0 \qquad (4.114)$$

and the boundary conditions:

$$C_b(0,\theta) \;=\; C_0 \qquad (4.115)$$

$$C_c(\xi,0,\theta) \;=\; C_b(\xi,\theta) \qquad (4.116)$$

$$C_c(\xi,1,\theta) \;=\; C_e(\xi,\theta) \qquad (4.117)$$

The solution of this model for frequency response proceeds as follows: firstly, transform equations (4.108), (4.111) and (4.113) with respect to θ employing (4.114). This leads to:

$$\frac{dC_b}{d\xi} + sC_b - X_b \left.\frac{dC_c}{d\zeta}\right|_{\zeta=0} \;=\; 0 \qquad (4.118)$$

$$\frac{d^2C_c}{d\zeta^2} - \left(\frac{\alpha\varepsilon_d s}{X_b}\right) C_c \;=\; 0 \qquad (4.119)$$

and $\quad sC_e + \dfrac{\delta\,X_b}{(a-\delta-\alpha\delta)\varepsilon_d} \left.\dfrac{dC_c}{d\zeta}\right|_{\zeta=1} \;=\; 0 \qquad (4.120)$

Define $\quad \psi = (\alpha\,\varepsilon_d\,s/X_b)^{0.5}\quad$ and solve (4.119):

$$C_c \;=\; A_1 \cosh(\psi\zeta) + A_2 \sinh(\psi\zeta) \qquad (4.121)$$

where A_1 and A_2 are constants to be determined. Boundary condition (4.116) gives

$$A_1 \;=\; C_b(\xi,s) \qquad (4.122)$$

and B.C. (4.117)

$$A_2 = \frac{C_e - C_b \cosh(\psi)}{\sinh(\psi)} \qquad (4.123)$$

These expressions for A_1 and A_2 may be substituted into (4.121) and the latter differentiated with respect to ζ. At $\zeta = 0$ this yields:

$$\frac{\partial C_c}{\partial \zeta}\Big|_{\zeta=0} = [C_e - C_b \cosh(\psi)]\, \psi/\sinh(\psi) \qquad (4.124)$$

and at $\zeta = 1$

$$\frac{\partial C_c}{\partial \zeta}\Big|_{\zeta=1} = C_b \psi \sinh(\psi) + \left[\frac{C_e - C_b \cosh(\psi)}{\sinh(\psi)}\right] \psi \cosh(\psi) \qquad (4.125)$$

Substitution of (4.125) into (4.120) leads to

$$C_e = C_b \frac{\delta X_b \psi [\cosh^2(\psi) - \sinh^2(\psi)]}{(1-\delta-\alpha\delta)\varepsilon_d\, s\, \sinh(\psi) + \delta X_b \psi \cosh(\psi)} \qquad (4.126)$$

and substitution of this expression and (4.124) into (4.118) yields

$$\frac{dC_b}{d\zeta} + \beta C_b = 0 \qquad (4.127)$$

where $\beta = \dfrac{(1-\delta-\alpha\delta)\varepsilon_d\, s\, [s \tanh(\psi) + \psi X_b] + \delta X_b\psi[s + X_b\psi \tanh\psi]}{(1-\delta-\alpha\delta)\varepsilon_d\, s \tanh(\psi) + \delta X_b \psi}$ (4.128)

Equation (4.127) may be solved directly, and applying the transformed B.C. given by (4.115) leads to:

$$C_b(\xi, s) = e^{-\beta\xi} \tag{4.129}$$

Now C_e is given in terms of C_b by equation (4.126), and for a thin cloud (i.e. small γ_c and α) the concentration at the tip of an aspirating probe is reasonably approximated by:

$$\bar{C} = \delta\,C_b + (1-\delta)\epsilon_d\,C_e\,/\,[\delta + (1-\delta)\epsilon_d] \tag{4.130}$$

A FORTRAN V listing of the model solution is given in Appendix B.

4.1.4 BPD Model

The bubble-phase dispersion or BPD model has been employed in the dynamic mode by other investigators (50), and the solution presented here is not new. It follows essentially the same pattern as that established by Kühne and Wippern (31), and is included mainly for completeness.

Formulation proceeds as follows: a material balance on a height increment Δz of the bubble phase leads to

$$\begin{bmatrix} accm \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convection} \end{bmatrix} + \begin{bmatrix} \text{gain by} \\ \text{interphase} \\ \text{transfer} \end{bmatrix} + \begin{bmatrix} \text{in-out} \\ \text{axial} \\ \text{dispersion} \end{bmatrix}$$

i.e.
$$\delta A_t \Delta z \frac{\partial C_b}{\partial t} = \delta A_t U_b [C_b|_z - C_b|_{z+\Delta z}] - (K_{be})_b \delta A_t \Delta z [C_b - C_e] - D_b \delta A_t [\frac{\partial C_b}{\partial z}|_z - \frac{\partial C_b}{\partial z}|_{z+\Delta z}] \tag{4.131}$$

Dividing by $\delta A_t \Delta z$ and letting Δz tend to zero:

$$\frac{\partial C_b}{\partial t} + U_b \frac{\partial C_b}{\partial z} - D_b \frac{\partial^2 C_b}{\partial z^2} + (K_{be})_b [C_b - C_e] = 0 \qquad (4.132)$$

and introducing θ and ξ:

$$\frac{\partial C_b}{\partial \theta} + \frac{\partial C_b}{\partial \xi} - N_b \frac{\partial^2 C_b}{\partial \xi^2} + X_b [C_b - C_e] = 0 \qquad (4.133)$$

where N_b is the number of bubble-phase dispersion units defined as $D_b/(U_b L_f)$. A material balance on the dense phase gives:

$$\begin{bmatrix} accm \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convection} \end{bmatrix} + \begin{bmatrix} \text{gain by} \\ \text{interphase} \\ \text{transfer} \end{bmatrix} + \begin{bmatrix} \text{in-out} \\ \text{by axial} \\ \text{dispersion} \end{bmatrix}$$

or $(1-\delta)\varepsilon_d A_t \Delta z \dfrac{\partial C_e}{\partial t} = (1-\delta)A_t U_d [C_e|_z - C_e|_{z+\Delta z}]$

$$+ (K_{be})_b \delta A_t \Delta z [C_b - C_e] - D_d(1-\delta)\varepsilon_d A_t [\frac{\partial C_e}{\partial z}|_z - \frac{\partial C_e}{\partial z}|_{z+\Delta z}] \quad (4.134)$$

Dividing by $(1-\delta)\varepsilon_d A_t \Delta z$ and taking the limit:

$$\frac{\partial C_e}{\partial t} + (\frac{U_d}{\varepsilon_d}) \frac{\partial C_e}{\partial z} - D_d \frac{\partial^2 C_e}{\partial z^2} - \frac{\delta(K_{be})_b}{(1-\delta)\varepsilon_d} [C_b - C_e] = 0 \qquad (4.135)$$

or in terms of θ and ξ:

$$\frac{\partial C_e}{\partial \theta} + (\frac{U_d}{\varepsilon_d U_b}) \frac{\partial C_e}{\partial \xi} - N_d \frac{\partial^2 C_e}{\partial \xi^2} - \frac{\delta X_b}{(1-\delta)\varepsilon_d} [C_b - C_e] = 0 \qquad (4.136)$$

The initial condition is:

$$C_b(\xi,0) = C_e(\xi,0) = 0 \qquad (4.137)$$

And the B.C.'s

$$C_b - N_b \frac{\partial C_b}{\partial \xi} = C_0 \text{ at } \xi = 0, \text{ all } \theta \qquad (4.138)$$

$$(\frac{U_d}{\epsilon_d U_b}) C_e - N_d \frac{\partial C_e}{\partial \xi} = 0 \text{ at } \xi = 0, \text{ all } \theta \qquad (4.139)$$

and C_b, C_e finite as $\xi \to \infty$ $\qquad (4.140)$

The solution to this model proceeds thus: equations (4.133) and (4.136) are transformed with respect to time, and with zero initial concentration in both phases this leads to:

$$- N_b \frac{d^2 C_b}{d\xi^2} + \frac{dC_b}{d\xi} + (X_b + s) C_b = X_b C_e \qquad (4.141)$$

and $\quad - N_d \frac{d^2 C_e}{d\xi^2} + U_r \frac{dC_e}{d\xi} + (X_e + s) C_e = X_e C_e \qquad (4.142)$

where U_r is defined as $U_d/(\epsilon_d U_b)$ and X_e as $\delta X_b/((1-\delta)\epsilon_d)$.

A transformation with respect to ξ is performed, using boundary conditions (4.138) and (4.139) and assuming C_0 to be an ideal impulse or Dirac delta function. The result, in matrix notation, is

$$\begin{bmatrix} (-N_b \nu^2 + \nu + X_b + s) & -X_b \\ -X_e & (- N_d \nu^2 + U_r \nu + X_e + s) \end{bmatrix} \begin{bmatrix} C_b \\ C_e \end{bmatrix} = \begin{bmatrix} 1 - N_b \nu C_{bo} \\ - N_d \nu C_{eo} \end{bmatrix} \qquad (4.143)$$

where the transformed distance variable is ν, and where $C_b(\xi=0,s)$ and $C_e(\xi=0,s)$ are abbreviated C_{bo} and C_{eo} respectively. The unknowns at this stage are C_{bo} and C_{eo}, and B.C. (4.140) must be applied to determine them.

The exponential factors of the response are given by the roots of the 2x2 determinant. This determinant may be written:

$$\Delta = N_b N_d \left[\nu^4 - \left(\frac{N_d + U_r N_b}{N_b N_d} \right) \nu^3 - \left(\frac{N_d(X_b+s) + N_b(X_e+s) - U_r}{N_b N_d} \right) \nu^2 \right.$$
$$\left. + \left(\frac{(X_e+s) + U_r(X_b+s)}{N_b N_d} \right) \nu + \frac{(X_b+s)(X_e+s) - X_b X_e}{N_b N_d} \right] \quad (4.144)$$

Let the roots of this expression be λ_i. For the conditions of interest, two of these roots have positive real components. These poles in the right-hand half-plane must coincide with zeros if B.C. (4.140) is to be satisfied. Solving equation (4.143) for C_b by Cramer's Rule gives:

$$C_b = \frac{1}{\Delta} \left[(-N_d \nu^2 + U_r \nu + X_e + s)(1 - N_b \nu C_{bo}) - X_b N_d \nu C_{eo} \right] \quad (4.145)$$

If the roots in the right-hand half-plane are λ_3 and λ_4, then this expression must take the form:

$$C_b = \frac{1}{\Delta} \left[C_{bo} N_b N_d (\nu-\lambda_3)(\nu-\lambda_4)(\nu-\gamma_1) \right] \quad (4.146)$$

where γ_1 is a constant to be determined.

Comparing coefficients of the numerator terms of (4.145) and (4.146) yields:

$$\lambda_3 + \lambda_4 + \gamma_1 \; = \; \frac{N_d + N_b \, U_r \, C_{bo}}{N_b \, N_d \, C_{bo}} \qquad (4.147)$$

$$- (\lambda_3\lambda_4 + \lambda_3\gamma_1 + \lambda_4\gamma_1) \; = \; \frac{N_b \, C_{bo} \, (X_e + s) + X_b \, N_d \, C_{eo} - U_r}{N_b \, N_d \, C_{bo}} \qquad (4.148)$$

$$- \lambda_3\lambda_4\gamma_1 \; = \; \frac{X_e + s}{N_b \, N_d \, C_{bo}} \qquad (4.149)$$

Similarly, solving (4.143) for C_e yields

$$C_e \; = \; \frac{1}{\Delta} \left[(1 - N_b \nu \, C_{bo}) X_e + (N_b \nu^2 - \nu - X_b - s)(N_d \nu \, C_{eo}) \right] \qquad (4.150)$$

and to satisfy (4.140):

$$C_e \; = \; \frac{1}{\Delta} \left[C_{eo} \, N_b \, N_d \, (\nu - \lambda_3)(\nu - \lambda_4)(\nu - \gamma_2) \right] \qquad (4.151)$$

Comparing coefficients as before leads to:

$$\lambda_3 + \lambda_4 + \gamma_2 \; = \; \frac{N_d \, C_{eo}}{N_b \, N_d \, C_{eo}} \qquad (4.152)$$

$$- (\lambda_3\lambda_4 + \lambda_3\gamma_2 + \lambda_4\gamma_2) \; = \; \frac{N_d \, C_{eo} \, (X_b + s) + N_b \, X_e \, C_{bo}}{N_b \, N_d \, C_{eo}} \qquad (4.153)$$

$$- \lambda_3\lambda_4\gamma_2 \; = \; \frac{X_e}{N_b \, N_d \, C_{eo}} \qquad (4.154)$$

Now equations (4.147) to (4.149) and (4.152) to (4.154) represent a system of six equations and four unknowns (C_{bo}, C_{eo}, γ_1 and γ_2). Any four equations may be used, however, since any combination of

four yields the same numerical values for the unknowns (this assertion was tested by using different equations in the computer model). A representative set of solutions for the four unknowns is:

$$C_{bo} = \frac{X_b + s + \lambda_3 \lambda_4 N_D}{N_4 \lambda_3 \lambda_4 \, [N_d(\lambda_3 + \lambda_4) - U_r]} \tag{4.155}$$

$$C_{eo} = \frac{X_e}{N_d \lambda_3 \lambda_4 \, [N_b(\lambda_3 + \lambda_4) - 1]} \tag{4.156}$$

$$\gamma_1 = \frac{X_b + s}{N_b N_d \, \lambda_3 \lambda_4 \, C_{bo}} \tag{4.157}$$

$$\gamma_2 = \frac{1}{N_b} - \lambda_3 - \lambda_4 \tag{4.158}$$

with all the unknowns accounted for, C_b may be written as

$$C_b(\nu, s) = \frac{C_{bo} N_b N_d \, (\nu - \lambda_3)(\nu - \lambda_4)(\nu - \gamma_1)}{N_b N_d \, (\nu - \lambda_1)(\nu - \lambda_2)(\nu - \lambda_3)(\nu - \lambda_4)}$$

Cancelling the factors containing λ_3 and λ_4 and inverse transforming with respect to ν:

$$C_b(\xi,s) = C_{bo} \left[\left(\frac{\lambda_1 - \gamma_1}{\lambda_1 - \lambda_2}\right) e^{\lambda_1 \xi} + \left(\frac{\lambda_2 - \gamma_1}{\lambda_2 - \lambda_1}\right) e^{\lambda_2 \xi} \right] \tag{4.159}$$

Similarly:

$$C_e(\xi,s) = C_{eo} \left[\left(\frac{\lambda_1 - \gamma_2}{\lambda_1 - \lambda_2}\right) e^{\lambda_1 \xi} + \left(\frac{\lambda_2 - \gamma_2}{\lambda_2 - \lambda_1}\right) e^{\lambda_2 \xi} \right] \tag{4.160}$$

Finally,

$$\bar{C} = \frac{\delta\, C_b + (1-\delta)\varepsilon_d\, C_e}{\delta + (1-\delta)\varepsilon_d} \tag{4.161}$$

A FORTRAN V listing of this solution is given in Appendix B. A warning is printed if the roots λ_3 and λ_4 do not both display positive real components.

4.1.5 MBT Model

As stated previously, the multiple bubble-track or MBT model is considered original to this study.

The model is shown in Figure 3.5 with five tracks or plug flow units in parallel for the bubble phase. In principle any number of plug flow units could be used, and one would usually employ the maximum number considered practical for any particular application. In this investigation the number of plug flow bubble tracks is fixed at five. The reason for this is that the

Univac library routine ROOTCP, which is used to find the
roots of the (complex) polynomial which emerges in the
model solution algorithm, has a practical limit on the order
of the polynomial it is able to handle. If the order of
the polynomial is too high, the range of numbers generated
in this routine becomes too large and an error condition
results. Five tracks in the MBT model generates a seventh-order
polynomial: this was found to be close to the ROOTCP practical
limit.

A material balance on an incremental height Δz of bubble track
i leads to:

$$
\begin{bmatrix} \text{accm} \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convection} \end{bmatrix} + \begin{bmatrix} \text{in-out} \\ \text{interphase} \\ \text{transfer} \end{bmatrix}
$$

or $\quad f_i \delta A_t \Delta z \dfrac{\partial C_{bi}}{\partial t} = f_i \delta A_t U_{bi} [C_{bi}|_z - C_{bi}|_{z+\Delta z}]$

$$
- (K_{be})_b f_i \delta A_t \Delta z [C_{bi} - C_e] \tag{4.162}
$$

where $f_i \delta$ is the fractional bubble hold-up of track i, or
equivalently, f_i is the fraction of δ assigned to track i.
Dividing by $f_i \delta A_t \Delta z$ and letting Δz tend to zero:

$$
\frac{\partial C_{bi}}{\partial t} + U_{bi} \frac{\partial C_{bi}}{\partial z} + (K_{be})_b [C_{bi} - C_e] = 0 \tag{4.163}
$$

Letting $\xi = z/L_f$ and $\theta = t(\bar{U}_b/L_f)$ where $\bar{U}_b$ is the average bubble velocity for all the tracks given by $\sum_i f_i U_{bi}$:

$$\frac{\partial C_{bi}}{\partial \theta} + U^+_{bi} \frac{\partial C_{bi}}{\partial \xi} + X_b [C_{bi} - C_e] = 0 \qquad (4.164)$$

where U^+_{bi} is a dimensionless relative velocity defined as $U_{bi}/\bar{U}_b$.

A material balance on the dense phase yields:

$$\begin{bmatrix} \text{accm} \end{bmatrix} = \begin{bmatrix} \text{in-out} \\ \text{convection} \end{bmatrix} + \begin{bmatrix} \text{in-out} \\ \text{axial} \\ \text{dispersion} \end{bmatrix} + \begin{bmatrix} \text{in-out} \\ \text{interphase} \\ \text{transfer} \end{bmatrix}$$

i.e. $(1-\delta)\epsilon_d A_t \Delta z \dfrac{\partial C_e}{\partial t} = (1-\delta) A_t U_d [C_e|_z - C_e|_{z+\Delta z}]$

$$- D_d (1-\delta)\epsilon_d A_t [\frac{\partial C_e}{\partial z}|_z - \frac{\partial C_e}{\partial z}|_{z+\Delta z}] + \sum_{i=1}^{5} (K_{be})_b f_i \delta A_t \Delta z [C_{bi} - C_e] \quad (4.165)$$

Dividing by $(1-\delta)\epsilon_d A_t \Delta z$ and taking the limit:

$$\frac{\partial C_e}{\partial t} + (\frac{U_d}{\epsilon_d})\frac{\partial C_e}{\partial z} - D_d \frac{\partial^2 C_e}{\partial z^2} - [\frac{\delta(K_{be})_b}{(1-\delta)\epsilon_d}] (\sum f_i C_{bi} - C_e) = 0 \qquad (4.166)$$

and introducing θ and ξ:

$$\frac{\partial C_e}{\partial \theta} + (\frac{U_d}{\epsilon_d \bar{U}_b}) \frac{\partial C_e}{\partial \xi} - N_d \frac{\partial^2 C_e}{\partial \xi^2} - [\frac{\delta X_b}{(1-\delta)\epsilon_d}] (\sum f_i C_{bi} - C_e) = 0 \quad (4.167)$$

where N_d is the number of dense phase dispersion units defined $D_d/(\bar{U}_b L_f)$. The initial conditions are, as before,

$$C_{bi}(\xi,0) = C_e(\xi,0) = 0 \quad \text{for all } i \qquad (4.168)$$

and the B.C.'s

$$C_{bi}(0,\theta) = C_o \quad \text{for all } i \tag{4.169}$$

$$(\frac{U_d}{\epsilon_d \bar{U}_b}) \, C_e - N_d \frac{\partial C_e}{\partial \xi} = 0 \quad \text{at } \xi = 0, \text{ all } \theta \tag{4.170}$$

and
$$\frac{\partial C_e}{\partial \xi} = 0 \text{ at } \xi = 1, \text{ all } \theta \tag{4.71}$$

The last two boundary conditions appear to be at odds with each other, since the bottom is treated as an open system and the top as a closed one (from a dispersion point of view). There is no particular physical reason for this choice - in fact the velocity in the dense phase is so small relative to that in the bubble phase (for the system studied here) that the choice either way is of little consequence.

The solution of this model is straightforward in principle, but involves some fairly complicated algebraic manipulations. The first step is to transform the time variable, employing the initial condition given by (4.168). Equation (4.164) gives:

$$U_{bi}^+ \frac{dC_{bi}}{d\xi} + (X_b + s) \, C_{bi} = X_b \, C_e \tag{4.172}$$

and (4.167) leads to:

$$-N_d \frac{d^2 C_e}{d\xi^2} + U_r \frac{dC_e}{d\xi} + (X_e + s) \, C_e = X_e \, \Sigma \, f_i \, C_{bi} \tag{4.173}$$

where U_r and X_e are defined as $U_d/(\epsilon_d \bar{U}_b)$ and $\delta \, X_b/((1-\delta)\epsilon_d)$ respectively.

The second step involves transforming with respect to ξ, using B.C.'s (4.169) and (4.170). Equation (4.172), in its transformed state, may be written

$$C_{bi}(\nu,s) = \frac{1 + b_i\,C_e(\nu,s)}{\nu + a_i}$$ (4.174)

where $a_i = (X_b + s)/U_{bi}^+$ (4.175)

and $b_i = X_b/U_{bi}^+$ (4.176)

Equation (4.173) leads to

$$(- N_d\nu^2 + U_r\nu + X_e + s)\,C_e - X_e\,\Sigma\,f_i\,C_{bi} = -N_d\,\nu\,C_{eo}$$ (4.177)

where C_{eo} is an abbreviation for $C_e(\xi = 0,s)$ and represents an unknown to be determined by applying the third B.C.

Equation (4.174) may be substituted into (4.177) to yield

$$C_e = \frac{-N_d\nu\,C_{eo} + X_e\,\Sigma\,f_i/(\nu+a_i)}{-N_d\nu^2 + U_r\nu + X_e + s - X_e\,\Sigma\,f_i\,b_i/(\nu+a_i)}$$ (4.178)

Several steps are omitted at this stage for brevity. It is clear, however, that (4.178) may be multiplied out to the form of a ratio of two polynomials in ν, and that C_e may be written in the form:

$$C_e = \frac{C_{eo}\nu^6 + \alpha_5 C_{eo}\nu^5 + (\alpha_4\,C_{eo} - \dfrac{\alpha_6\,X_e}{N_d})\nu^4 + (\alpha_3\,C_{eo} - \dfrac{\alpha_7\,X_e}{N_d})\nu^3}{(\nu-\lambda_1)(\nu-\lambda_2)(\nu-\lambda_3)(\nu-\lambda_4)} \cdots$$

$$\cdots \frac{+ (\alpha_2\,C_{eo} - \dfrac{\alpha_8\,X_e}{N_d})\nu^2 + (\alpha_1\,C_{eo} - \dfrac{\alpha_9\,X_e}{N_d})\nu - (\dfrac{\alpha_{10}\,X_e}{N_d})}{(\nu-\lambda_5)(\nu-\lambda_6)(\nu-\lambda_7)}$$ (4.179)

where λ_i are the roots of

$$\alpha_{16}\nu^7 + \alpha_{17}\nu^6 + \alpha_{18}\nu^5 + \alpha_{19}\nu^4 + \alpha_{20}\nu^3 + \alpha_{21}\nu^2 + \alpha_{22}\nu + \alpha_{23} = 0 \qquad (4.180)$$

and the α_i terms are defined in Table 4.1. Equation (4.179) may be split into partial fractions and inverse transformed with respect to ν to give:

$$C_e(\xi,s) = C_{eo} \sum_{k=1}^{7} (\frac{\beta_k}{\rho_k})e^{\lambda_k\xi} - \sum_{k=1}^{7} (\frac{\gamma_k}{\rho_k})e^{\lambda_k\xi} \qquad (4.181)$$

where the β_k, γ_k and ρ_k terms are also defined in Table 4.1. Differentiating (4.181) with respect to ξ and applying boundary condition (4.171) leads to:

$$C_{eo} = \sum_{k=1}^{7} (\frac{\gamma_k}{\rho_k})\lambda_k e^{\lambda_k} / \sum_{k=1}^{7} (\frac{\beta_k}{\rho_k})\lambda_k e^{\lambda_k} \qquad (4.182)$$

With C_{eo} specified by (4.182), equation (4.181) represents a solution for $C_e(\xi,s)$. To solve for $C_{bi}(\xi,s)$, integrate (4.172) to give:

$$C_{bi} = e^{-a_i\xi} + b_i e^{-a_i\xi} \int_0^\xi C_e(\xi^1,s) e^{a_i\xi^1} d\xi^1 \qquad (4.183)$$

where ξ^1 represents a dummy variable. Substitute (4.181) into (4.183) and integrate to obtain

$$C_{bi} = e^{-a_i\xi} + b_i e^{-a_i\xi} [\sum_{k=1}^{7} \frac{C_{eo}\beta_k - \gamma_k}{\rho_k(a_i+\gamma_k)} (e^{(a_i+\gamma_k)\xi} - 1)] \qquad (4.184)$$

TABLE 4.1

$\qquad\qquad + f_4\,(a_1\, a_2\, a_3 + a_1\, a_2\, a_5 + a_1\, a_3\, a_5 + a_2\, a_3\, a_5)$
$\qquad\qquad + f_5\,(a_1\, a_2\, a_3 + a_1\, a_2\, a_4 + a_1\, a_3\, a_4 + a_2\, a_3\, a_4)$

TABLE 4.1   (continued)

$$\alpha_{10} = f_1 (a_2\, a_3\, a_4\, a_5) + f_2 (a_1\, a_3\, a_4\, a_5) + f_3 (a_1\, a_2\, a_4\, a_5)$$
$$+ f_4 (a_1\, a_2\, a_3\, a_5) + f_5 (a_1\, a_2\, a_3\, a_4)$$

$\alpha_{11} - \alpha_{15} = \alpha_6 - \alpha_{10}$ with f_i replaced by $f_i b_i$

$$\alpha_{16} = - N_D$$

$$\alpha_{17} = - \alpha_5 N_D + U_r$$

$$\alpha_{18} = - \alpha_4 N_D + \alpha_5 U_r + (X_e + s)$$

$$\alpha_{19} = - \alpha_3 N_D + \alpha_4 U_r + \alpha_5 (X_e + s) - \alpha_{11} X_e$$

$$\alpha_{20} = - \alpha_2 N_D + \alpha_3 U_r + \alpha_4 (X_e + s) - \alpha_{12} X_e$$

$$\alpha_{21} = - \alpha_1 N_D + \alpha_2 U_r + \alpha_3 (X_e + s) - \alpha_{13} X_e$$

$$\alpha_{22} = \alpha_1 U_r + \alpha_2 (X_e + s) - \alpha_{14} X_e$$

$$\alpha_{23} = \alpha_1 (X_e + s) - \alpha_{15} X_e$$

$$\beta_i = \lambda_i^{\,6} + \alpha_5 \lambda_i^{\,5} + \alpha_4 \lambda_i^{\,4} + \alpha_3 \lambda_i^{\,3} + \alpha_2 \lambda_i^{\,2} + \alpha_1 \lambda_i$$
$$(i = 1 \text{ to } 7)$$

$$\gamma_i = (\alpha_6 \lambda_i^{\,4} + \alpha_7 \lambda_i^{\,3} + \alpha_8 \lambda_i^{\,2} + \alpha_9 \lambda_i + \alpha_{10}) \left(\frac{X_e}{N_D}\right)$$
$$(i = 1 \text{ to } 7)$$

$$\rho_i = (\lambda_i - \lambda_1)(\lambda_i - \lambda_2)(\lambda_i - \lambda_3)(\lambda_i - \lambda_4)(\lambda_i - \lambda_5)(\lambda_i - \lambda_6)(\lambda_i - \lambda_7)$$
$$(i = 1 \text{ to } 7; \ i \neq k)$$

The average concentration at the probe tip is then given

by:

$$\bar{C} = \frac{\delta \Sigma f_i \, C_{bi} + (1-\delta)\epsilon_d \, C_e}{\delta + (1-\delta)\epsilon_d} \qquad (4.185)$$

A FORTRAN V listing of this solution is given in Appendix B.

4.2 Sparger Model Formulation and Numerical Solution

To the best of the author's knowledge, no models describing a

split feed fluidised bed system have appeared in the open

literature. Both the models put forward here are considered

original.

The sparger models are formulated in much the same way as the

general models. The solution, however, is by finite differences

in the time domain. The sparger models are not amenable to any

reasonable analytical solution in the Laplace or frequency domains

because of the discontinuity in model parameters at some elevation

in the bed.

4.2.1 LMBP Model

The mathematical formulation of the LMBP model, shown in Figure 3.6,

is identical to that for the MVD model for the upper and lower

regions in isolation. The differential equation resulting from

a material balance on an incremental height of the bubble phase

is:

$$\frac{\partial C_b}{\partial t} + U_b \frac{\partial C_b}{\partial z} + (K_{be})_b \left[C_b - C_e\right] = 0 \qquad (4.186)$$

Now U_b and $(K_{be})_b$ change abruptly at a height L_s. If the bubble velocity in the lower region is written U_{bl} and its counterpart in the upper U_{bu}, and similarly $(K_{be})_b$ in each region is abbreviated K_l and K_u, then:

$$\frac{\partial C_b}{\partial t} + U_{bl} \frac{\partial C_b}{\partial z} + K_l \left[C_b - C_e\right] = 0 \qquad (4.187)$$

for $0 \leq z < L_s$, and

$$\frac{\partial C_b}{\partial t} + U_{bu} \frac{\partial C_b}{\partial z} + K_u \left[C_b - C_e\right] = 0 \qquad (4.188)$$

for $L_s \leq z \leq L_f$. For the dense phase:

$$\frac{\partial C_e}{\partial t} + \left(\frac{U_d}{\epsilon_d}\right) \frac{\partial C_e}{\partial z} - \frac{\delta K_s}{(1-\delta)\epsilon_d} \left[C_b - C_e\right] - D_d \frac{\partial^2 C_e}{\partial z^2} = 0 \qquad (4.189)$$

for $0 \leq z < L_s$ and

$$\frac{\partial C_e}{\partial t} + \left(\frac{U_d}{\epsilon_d}\right) \frac{\partial C_e}{\partial z} - \frac{\delta K_u}{(1-\delta)\epsilon_d} \left[C_b - C_e\right] - D_d \frac{\partial^2 C_e}{\partial z^2} = 0 \qquad (4.190)$$

for $L_s \leq z \leq L_f$. The initial condition is:

$$C_b(z,0) = C_e(z,0) = 0 \qquad (4.191)$$

and the boundary conditions:

$$C_b(0,t) = 0 \tag{4.192}$$

$$C_b(L_s,t) = C_0 \tag{4.193}$$

$$\left.\frac{\partial C_e}{\partial z}\right|_{z=0} = 0 \quad \text{for all } t \tag{4.194}$$

$$\text{and } \left.\frac{\partial C_e}{\partial z}\right|_{z=L_f} = 0 \quad \text{for all } t \tag{4.195}$$

These equations are solved directly by a Crank-Nicholson finite difference technique as described by Carnahan, Luther and Wilkes (100). In essence, this method involves describing the partial derivatives of a function $f(x,y)$ on a grid with spacings Δx and Δy at a point $(x, y + \frac{1}{2} \Delta y)$ by:

$$\frac{\partial f}{\partial x} \doteq \frac{f(x+\Delta x,y) - f(x-\Delta x,y)}{4 \Delta x} + \frac{f(x+\Delta x,y+\Delta y) - f(x-\Delta x,y+\Delta y)}{4 \Delta x} \tag{4.196}$$

$$\text{and } \frac{\partial f}{\partial y} \doteq \frac{f(x,y+\Delta y) - f(x,y)}{\Delta y} \tag{4.197}$$

This method is correct to second order differences in both independent variables, and the implicit computational procedure thus defined displays stability characteristics far superior to those of the related explicit procedures (101). The implicit procedure requires the solution of an MxM matrix in x for each

Δy increment, where M is the number of x-nodes. This matrix appears in tridiagonal form, however, and may be efficiently solved by the application of a suitable recursion formula (100).

Equation (4.187), in finite difference form, becomes:

$$\frac{C_{b\ i,n+1} - C_{b\ i,n}}{\Delta t} + U_b \frac{C_{b\ i+1,n+1} - C_{b\ i-1,n+1} + C_{b\ i+1,n} - C_{b\ i-1,n}}{4\ \Delta z}$$

$$+ K_1 \left[\frac{C_{b\ i,n+1} + C_{b\ i,n}}{2} - C_{e\ i,n}\right] = 0 \qquad (4.198)$$

and on rearrangement:

$$\left(\frac{U_{b1}\ \Delta t}{4\ \Delta z}\right) C_{b\ i+1,n+1} + \left(1 + \frac{\Delta t\ K_1}{2}\right) C_{b\ i,n+1} - \left(\frac{U_{b1}\ \Delta t}{4\ \Delta z}\right) C_{b\ i-1,n+1}$$

$$= -\left(\frac{U_{b1}\ \Delta t}{4\ \Delta z}\right) C_{b\ i+1,n} + \left(1 - \frac{\Delta t\ K_1}{2}\right) C_{b\ i,n} + \left(\frac{U_{b1}\ \Delta t}{4\ \Delta z}\right) C_{b\ i-1,n} \qquad (4.199)$$

where the subscript i refers to the number of Δz increments and n to Δt increments. Equation (4.188) may be written:

$$\left(\frac{U_{bu}\ \Delta t}{4\ \Delta z}\right) C_{b\ i+1,n+1} + \left(1 + \frac{\Delta t\ K_u}{2}\right) C_{b\ i,n+1} - \left(\frac{U_{bu}\ \Delta t}{4\ \Delta z}\right) C_{b\ i-1,n+1}$$

$$= -\left(\frac{U_{bu}\ \Delta t}{4\ \Delta z}\right) C_{b\ i+1,n} + \left(1 - \frac{\Delta t\ K_u}{2}\right) C_{b\ i,n} + \left(\frac{U_{bu}\ \Delta t}{4\ \Delta z}\right) C_{b\ i-1,n} \qquad (4.200)$$

Equation (4.189) becomes:

$$\frac{C_{e\ i,n+1} - C_{e\ i,n}}{\Delta t} + (\frac{U_d}{\varepsilon_d}) \frac{C_{e\ i+1,n+1} - C_{e\ i-1,n+1} + C_{e\ i+1,n} - C_{e\ i-1,n}}{4\ \Delta z}$$

$$- \frac{\delta\ K_1}{(1-\delta)\varepsilon_d} \left[C_{b\ i,n} - \frac{C_{e\ i,n+1} - C_{e\ i,n}}{2} \right]$$

$$- D_d \frac{C_{e\ i+1,n+1} - 2\ C_{e\ i,n+1} + C_{e\ i-1,n+1} + C_{e\ i+1,n} - 2\ C_{e\ i,n} + C_{e\ i-1,}}{2(\Delta z)^2}$$

$$(4.201)$$

and may be rearranged to:

$$(\frac{U_d\ \Delta t}{\varepsilon_d\ 4\Delta z} - \frac{D_d\ \Delta t}{2\ \Delta z^2})\ C_{e\ i+1,n+1} + (1 + \frac{\delta\ K_1\ \Delta t}{(1-\delta)\varepsilon_d 2} + \frac{D_d\ \Delta t}{\Delta z^2})C_{e\ i,n+1}$$

$$+ (- \frac{U_d\ \Delta t}{\varepsilon_d\ 4\Delta z} - \frac{D_d\ \Delta t}{2\Delta z^2})\ C_{e\ i-1,n+1}$$

$$= (- \frac{U_d\ \Delta t}{\varepsilon_d\ 4\Delta z} + \frac{D_d\ \Delta t}{2\Delta z^2})\ C_{e\ i+1,n} + (1 - \frac{\delta\ K_1\ \Delta t}{(1-\delta)\varepsilon_d 2} - \frac{D_d\ \Delta t}{\Delta z^2})\ C_{e\ i,n}$$

$$+ (\frac{U_d\ \Delta t}{\varepsilon_d\ 4\Delta z} + \frac{D_d\ \Delta t}{2\ \Delta z^2})\ C_{e\ i-1,n} + \frac{\delta\ K_1\ \Delta t}{(1-\delta)\varepsilon_d}\ C_{b\ i,n} \qquad (4.202)$$

Equation (4.190) may be written in the same form, with K_u replacing K_1. The node boundaries are accounted for as follows:

(i) At the node corresponding to z=0, C_b is constrained to be zero at all times. C_e is accounted for by creating an artificial node at $(-\Delta z)$, and letting $C_{e\ -1,n} = C_{e\ 1,n}$. This is effectively an application of B.C. (4.194).

(ii)   At the top of the bed, i.e. $M\Delta z = L_f$, a backward

difference on the interval $(M-1,M)$ is used for

C_b. An artificial node is created at $(M+1)$, and

$C_{e\ M+1,n} = C_{e\ M-1,n}$ as required by (4.195).

At the node corresponding to L_s, C_b is constrained to:

$$C_b(L_s,t) = C_0(t) \qquad\qquad (4.203)$$

A FORTRAN V listing of the solution is given in Appendix B.

4.2.1.1 Numerical Solution Details

In the early stages of the development of numerical solutions

such as the one presented here, the models were excited

(numerically) by a very sharp stimulus function $C_0(t)$. The

response to such an input displayed damped oscillations, which

according to Bettencourt et. al. (102), are typical of most finite

difference procedures. Decreasing the sharpness of the exciting

function was found to stabilise the numerical response, though

excessive flattening of this function would clearly lead to a

loss of resolution in the parameter estimation procedure. A

suitable compromise for $C_0(t)$ was found to be:

$$C_0(t) = t^4 \exp(-20\ t/\tau_p)$$

where t is time in seconds and τ_p represents the lumped process

time constant. This represents an ideal impulse convolved with

four perfectly mixed stages in series, each with a time

constant of 1/20 th of that of the process. With this input,

a reasonable number of time and distance increments (200 x 100

respectively) was found to produce a smooth frequency response

to frequencies significantly higher than those obtainable

from the experimental apparatus. An investigation into the

influence of the magnitudes of Δt and Δz showed that the model

response is relatively insensitive to increases in the number

of nodes beyond about 100 Δt's by 50 Δz's.

A problem associated with the truncation of the (time-domain)

response at some finite time and the actual numerical trans=

formation into the frequency domain will not be described in

this section. The experimental data and the time-domain model

response are equivalent from a transformation point of view,

and the procedures developed for this manipulation are described

in the context of experimental data processing in section 4.3.

4.2.2 Laterally Segregated Bubble-Phase Model

A material balance over a height increment of either bubble

phase yields results similar to that for the MVD model. For

the grid bubbles:

$$\frac{\partial C_{bg}}{\partial t} + U_{bg} \frac{\partial C_{bg}}{\partial z} + K_{gl} \left[C_{bg} - C_e \right] = 0 \qquad (4.205)$$

for $0 \leq z < L_s$, and

$$\frac{\partial C_{bg}}{\partial t} + U_{bg} \frac{\partial C_{bg}}{\partial z} + K_{gu} \left[C_{bg} - C_e \right] = 0 \qquad (4.206)$$

for $L_s \le z \le L_f$. The subscript g refers to bubbles originating from the grid. For bubbles from the sparger:

$$\frac{\partial C_{bs}}{\partial t} + U_{bs} \frac{\partial C_{bs}}{\partial z} + K_s \left[C_{bs} - C_e \right] = 0 \qquad (4.207)$$

The dense phase material balance is formulated thus:

$$\left[\begin{array}{c} \text{accm} \end{array} \right] = \left[\begin{array}{c} \text{in-out} \\ \text{convection} \end{array} \right] + \left[\begin{array}{c} \text{net gain} \\ \text{from grid} \\ \text{bubbles} \end{array} \right] + \left[\begin{array}{c} \text{net gain} \\ \text{from sparger} \\ \text{bubbles} \end{array} \right]$$

$$+ \left[\begin{array}{c} \text{in-out} \\ \text{by axial} \\ \text{dispersion} \end{array} \right]$$

i.e.
$$(1-\delta) \epsilon_d \, A_t \, \frac{\partial C_e}{\partial t} = (1-\delta) \, A_t \, U_d \left[C_{e|z} - C_{e|z+\Delta z} \right]$$

$$+ K_{gk} \, f_{gk} \delta \, A_t \, \Delta z \left[C_{bg} - C_e \right] + K_s \, f_s \, \delta \, A_t \, \Delta z \left[C_{bs} - C_e \right]$$

$$- D_d \, (1-\delta) \epsilon_d \, A_t \left[\frac{\partial C_e}{\partial z} \Big|_z - \frac{\partial C_e}{\partial z} \Big|_{z+\Delta z} \right] \qquad (4.208)$$

where f_s and f_g are fractions of the total bubble holup assigned to the sparger and grid bubbles respectively, and the subscrip k represents l below the sparger and u above. Below the sparger f_s is zero. Dividing by $(1-\delta) \epsilon_d \, \Delta z$ and letting Δz tend to zero:

$$\frac{\partial C_e}{\partial t} + \left(\frac{U_d}{\varepsilon_d}\right) \frac{\partial C_e}{\partial z} - D_d \frac{\partial^2 C_e}{\partial z^2} + \frac{\delta \, (f_s \, K_s + f_{gk} \, K_{gk})}{(1-\delta)\varepsilon_d} \, C_e$$

$$= \frac{\delta}{(1-\delta)\varepsilon_d} \left[f_s \, K_s \, C_{bs} + f_{gk} \, K_{gk} \, C_{bg} \right] \qquad (4.209)$$

The finite difference form of (4.205) is:

$$\left(\frac{U_{bg} \, \Delta t}{4\Delta z}\right) C_{bg \ i+1,n+1} + \left(1 + \frac{K_{gl} \, \Delta t}{2}\right) C_{bg \ i,n+1} - \left(\frac{U_{bg} \, \Delta t}{4\Delta z}\right) C_{bg \ i-1,n+1}$$

$$= - \left(\frac{U_{bg} \, \Delta t}{4\Delta z}\right) C_{bg \ i+1,n} + \left(1 - \frac{K_{gl} \, \Delta t}{2}\right) C_{bg \ i,n} + \left(\frac{U_{bg} \, \Delta t}{4\Delta z}\right) C_{bg \ i-1,n}$$

$$+ \ K_{gl} \, \Delta t \, C_{e \ i,n} \qquad (4.210)$$

Equation (4.206) and (4.207) may be written in the same form, with the appropriate subscripts. The finite difference version of (4.209) is:

$$\left(\frac{U_d}{\varepsilon_d} \frac{\Delta t}{4\Delta z} - \frac{D_d \, \Delta t}{2\Delta z^2}\right) C_{e \ i+1,n+1} + \left(1 + \frac{D_d \, \Delta t}{\Delta z^2} + \frac{\delta \Delta t \, (f_s \, K_s + f_{gk} \, K_{gk})}{2(1-\delta)\varepsilon_d}\right) C_{e \ i,n+1}$$

$$+ \left(- \frac{U_d}{\varepsilon_d} \frac{\Delta t}{4\Delta z} - \frac{D_d \, \Delta t}{2\Delta z^2}\right) C_{e \ i-1,n+1}$$

$$= \left(- \frac{U_d}{\varepsilon_d} \frac{\Delta t}{4\Delta z} + \frac{D_d \, \Delta t}{2\Delta z^2}\right) C_{e \ i+1,n} + \left(1 - \frac{D_d \, \Delta t}{\Delta z^2} - \frac{\delta \Delta t (f_s \, K_s + f_{gk} \, K_{gk})}{2(1-\delta)\varepsilon_d}\right) C_{e \ i,n}$$

$$+ \left(\frac{U_d}{\varepsilon_d} \frac{\Delta t}{4\Delta z} + \frac{D_d \, \Delta t}{2\Delta z^2}\right) C_{e \ i-1,n} + \frac{\delta \, \Delta t}{(1-\delta)\varepsilon_d} \left(f_{gk} \, K_{gk} \, C_{bg \ i,n} + f_s \, K_s \, C_{bs \ i,n}\right) \qquad (4.211)$$

The initial condition is:

$$C_{bg}(z,0) = C_{bs}(z,0) = C_e(z,0) = 0 \tag{4.212}$$

and the boundary conditions:

$$C_{bg}(0,t) = 0 \tag{4.213}$$

$$C_{bs}(L_s,t) = C_0(t) \tag{4.214}$$

$$\left.\frac{\partial C_e}{\partial z}\right|_{z=0} = 0 \text{ for all } t \tag{4.215}$$

$$\left.\frac{\partial C_e}{\partial z}\right|_{z=L_f} = 0 \text{ for all } t \tag{4.216}$$

The node boundaries are accounted for as follows:

   (i)   At $z = 0$, C_b is constrained to be zero at all times. Boundary condition (4.215) is accounted for by letting $C_{e\,-1,n} = C_{e\,1,n}$.

   (ii)   At $z = L_f$, backward differences are used on $(M-1,M)$ for C_{bg} and C_{bs}. B.C. (4.216) is accounted for by letting $C_{e\,M-1,n} = C_{e\,M+1,n}$.

   (iii)   At $z = L_s$, C_{bs} is constrained to be equal to $C_0(t)$.

The discussion on the shape of the exciting function and
numerical stability of the response in the preceeding section
applies equally well to this model, and a FORTRAN V listing of
the solution is given in Appendix B.

4.3   Data Processing and Information Flow

In this section the processing of experimental data to frequency
response form is described, and the method of comparison and
parameter optimisation is discussed.

An overall information flow diagram is given as Figure 4.1.
A dynamic stimulus is applied to the actual fluidised bed, and
this stimulus, together with the system response, is processed
by a Fourier transform (FT) routine to yield the experimental
transfer function $G_e(jw)$. (It is understood that both the
stimulus and the response are such that the form of the FT
given by equation (4.5) is valid). The model frequency response
is generated either directly (as in section 4.1) or indirectly
as shown in Figure 4.1, depending on whether the model has been
solved in the frequency or time domains. The model transfer
function $G_m(jw)$ is subsequently compared to $G_e(jw)$, and the
model parameters are changed and $G_m(jw)$ re-evaluated until the
greatest possible degree of closure has been obtained.

The rest of this section is taken up with a discussion of the
Fourier transform routine and a brief description of the parameter
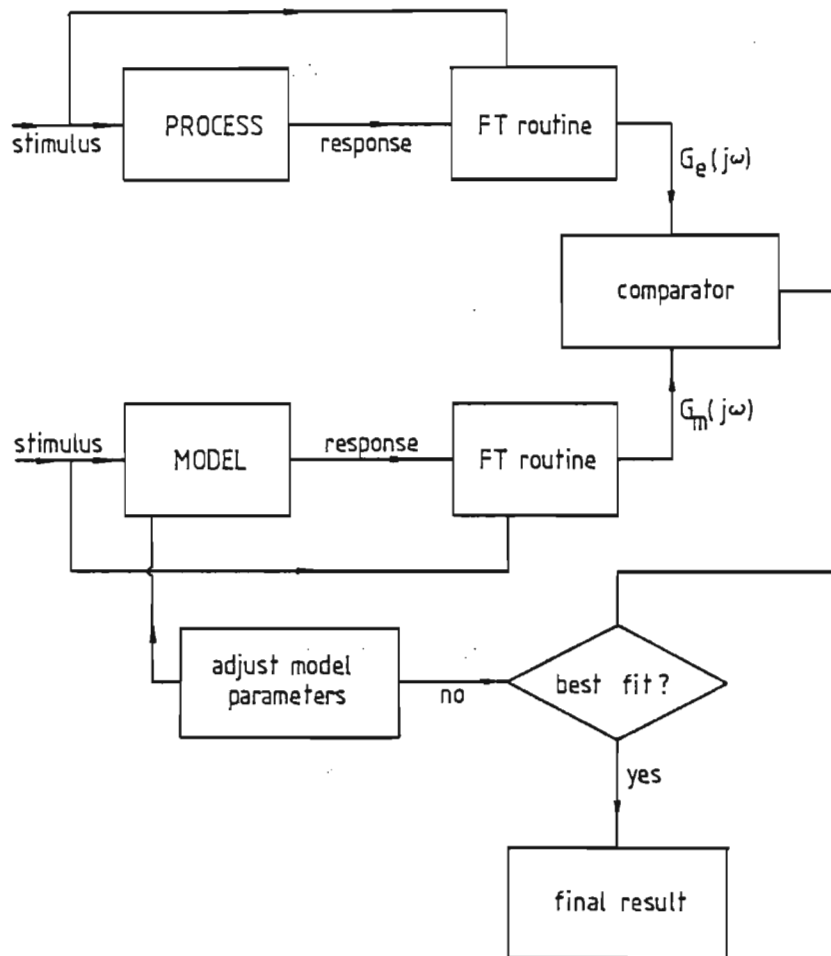

FIGURE 4.1   INFORMATION FLOW STRATEGY

adjustment strategy. This pair of data processing steps essentially completes the software development matrix.

4.3.1 Fourier Transform Routine

It is well known that highly efficient numerical Fourier Transform routines are available commercially. None was immediately accessible to the author at the time of this investigation, however, and it was decided to develop an FT routine as applied to this problem from first principles.

The development details and a listing of the routine are given in Appendix C. The main features incorporated to minimise information loss in the face of numerical integration (to infinity) are:

(i)   Integration is performed by an overlapping double application of Simpson's rule.

(ii)   An analytical decay tail is fitted to the last 20% of the data. The integration is extended to infinity on this basis.

Appendix C also includes the results of a test against a simple tanks-in-series model, and this routine is shown to perform well even at frequencies significantly higher than those obtainable from the experimental apparatus.

4.3.2 Parameter Optimisation Routine

The parameter adjustment strategy is based on the Nelder
and Mead (103) sequencial search algorithm. The procedure
involves the minimisation a function of n variables by
comparison of function values at the (n+1) vertices of a
general simplex. This simplex adapts to local landscape and
contracts on the final minimum. The overall procedure has been
shown (103) to be effective and computationally compact.

The objective function to be minimised is set up as follows:

$$\phi = \sum_w (Re\ [G_e(jw)] - Re\ [G_m(jw)])^2$$

$$+ \sum_w (Im[G_e(jw)] - Im[G_m(jw)])^2 \qquad (4.217)$$

where Re and Im specify real and imaginary components respectively.
This formulation is consistent with least squares in the time
domain, as required by equation (4.7).

Listings of the sequencial search routine and the objective
function subroutine are given in Appendix D. A listing of the
main driving program is included for completeness.

CHAPTER 5

EXPERIMENTAL APPARATUS, PROCEDURE AND STRATEGY

5.1   Description of the Fluidised Beds

Two transparent cylindrical cold models were used, with internal

diameters 0.05 m and 0.64 m. The small column was studied essentially

as a reference point, since the pilot plant reactors at Sasol on

which abundant synthesis information was available were of a similar

dimension. An additional column with diameter 0.14 m was also

available, though this was used only for various validation procedures

and will not be described in any detail. The fluidising medium in all

cases was air and the powder finely divided iron oxide.

5.1.1   0.05 m Cold Model

The small unit consisted of a 6.70 m high glass tube with an

internal diameter of 0.05 m (2'') as shown in Figure 5.1. The

gas distributor was a porous metal plate with linear pressure

drop vs gas velocity characteristics, and the plenum chamber was

filled with 6 mm glass beads to reduce dead volume. Pressure

taps were distributed along the side of the rig as shown in

Figure 5.1, and these were connected to a bank of Hg-manometers.

Pipe-cleaners were inserted into the pressure points to keep the

pressure lines free of solids. Exhaust gas passed through an

absolute filter to atmosphere, and this filter was periodically

blown back to return any accumulated fines to the bed. Ports for

the introduction of gas sampling probes were included at five

levels in the glass column and in the plenum chamber as shown.

5.1.2   0.64 m Cold Model

The larger of the cold models was 6.14 m in height and had an

internal diameter of 0.64 m. It was built up of six perspex sections

porous metal gas distributor:
pressure drop vs gas
velocity
FIGURE 5.1   0.05 m COLD MODEL

as shown in Figure 5.2. The gas distributor consisted of

a multi-orifice plate, the exact details of which are withheld

for proprietary reasons. The plenum chamber was filled, as

far as possible, with plastic bottles to decrease dead volume.

Pairs of dummy vertical coils could be inserted to reduce the

hydraulic diameter of the system, and a gas sparger could be

introduced between the bottom of the coil bank and the main gas

distributor. The exact details of the coils and the sparger

are withheld for proprietary reasons.

Exhaust gas passed through a single-stage cyclone and the

overhead gas was filtered and exhausted to atmosphere. Fines

from the filter were periodically returned to the bed. The

cyclone underflow was discharged near the bottom of the bed from

a 0.05 m dipleg terminating in a flapper valve arrangement.

Pressure taps were distributed as shown in Figure 5.2, and

pressures were measured by Hg manometers as before. The

pressure points extended about 0.1 m into the bed to avoid any

anomolous wall backflow effects. Ports for gas sampling probes

were included at five locations on the column and in the plenum

chamber.

5.1.3   Air Supply and Metering System

Supply air was received at about 550 kPa (abs) and entered the

fluidised beds at between 100 and 150 kPa (abs), depending on the

powder charge. (Note that atmospheric pressure in Sasolburg is
FIGURE 5.2   0.64 m COLD MODEL

only about 86 kPa (abs)). Air received at 550 kPa was water-saturated at this pressure - the humidity level of the air in the fluidised beds was correspondingly lower and approximately constant.

The gas metering system consisted of a standard orifice and differential pressure (DP) cell arrangement. Frequent calibrations were carried out to guard against zero and range errors in the latter, and several different orifice sizes were employed to cover the wide range of flows required. For the smaller of the cold models orifice metering was found to be unsatisfactory at low velocities - a bellows-type gas meter measuring the exhaust from the filters was used instead.

The pressure drop across the bed means that the superficial gas velocity actually varies from the bottom to the top. In all cases an average superficial velocity was calculated on the basis of pressure at half the bed height, and it is this average U_o that is quoted throughout the text.

5.1.4 Powder Characterisation

The powder was finely ground iron oxide. This material had a negligible porosity and a particle density of 5190 kg/m^3 as determined by xylene displacement. The volume mean particle size, as measured by a technique involving low-angle forward scattering of light from a laser source [104], came to 40 μ.

Minimum fluidisation velocity for this material was determined
by plotting bed pressure drop against gas velocity on logarithmic
co-ordinates. This plot is shown in Figure 5.3 (for decreasing
velocity), and U_{mf} was found to be about 0.0025 m/s.
FIGURE 5.3   MINIMUM FLUIDISATION PLOT

5.2 The Development of RTD Hardware

5.2.1 Tracer Gas Type and Detection

A rapid, continuous tracer detection system was deemed

necessary for this study. A flame ionisation detector (FID)

was selected - this technique involves the combustion of sample

and carrier gas streams in a hydrogen flame. The electrical

conductivity of this flame gives an indication of the amount of

combustible material present, and this system is accordingly

limited to the use of combustible tracers such as hydrocarbons.

The possibility of tracer adsorption on   the solid particles

exists, and the detection system is an atmospheric one. A

pressure somewhat above ambient in the column is therefore

required to provide a driving force for sampling, and pressure

fluctuations associated with bubble movement are expected to

show up as noise in the FID signal.

It was decided that both the process input and output signals

should be measured to avoid any assumption on the exact form of

the input. A pair of Varian 1400 gas chromatographs were obtained

and adapted for direct use of the flame ionisation detectors.

The tracer gas selected was methane. This hydrocarbon was

considered least likely to adsorb, and tests were carried out to

establish the suitability or otherwise of this gas as a tracer.

Adsorption tests over two grades of powder were conducted with

helium as a reference gas. The powders were neat iron oxide and iron oxide mixed with finely ground carbon (to simulate catalyst ageing), and the adsorption results are shown in Figures 5.4 and 5.5 respectively. It is clear that methane adsorbs strongly in the presence of carbon, but does not adsorb on the neat iron oxide powder.

5.2.2 Sampling System

The physical setup of the process and the two continuous gas sampling systems is shown in Figure 5.6. Also shown is an interpretation of the steps involved in terms of transfer functions. The output signals $Y_1(s)$ and $Y_2(s)$ are observable, while the overall aim is to measure the process transfer function $G_p(s)$. According to the rules of block diagram algebra:

$$Y_1(s) = G_{1s}(s) X(s) \qquad (5.1)$$

and $\qquad Y_2(s) = G_p(s) G_{us}(s) X(s) \qquad (5.2)$

Solving for $G_p(s)$ in terms of $Y_1(s)$ and $Y_2(s)$ leads to:

$$G_p(s) = \frac{Y_2(s) \cdot G_{1s}(s)}{Y_1(s) \cdot G_{us}(s)} \qquad (5.3)$$

In other words, $G_p(s)$ can only be extracted from $Y_1(s)$ and $Y_2(s)$ if the upper and lower system transfer functions $G_{us}(s)$ and $G_{1s}(s)$ are known or equal. The dynamics of the sampling systems should be as fast and well balanced as possible to maximise

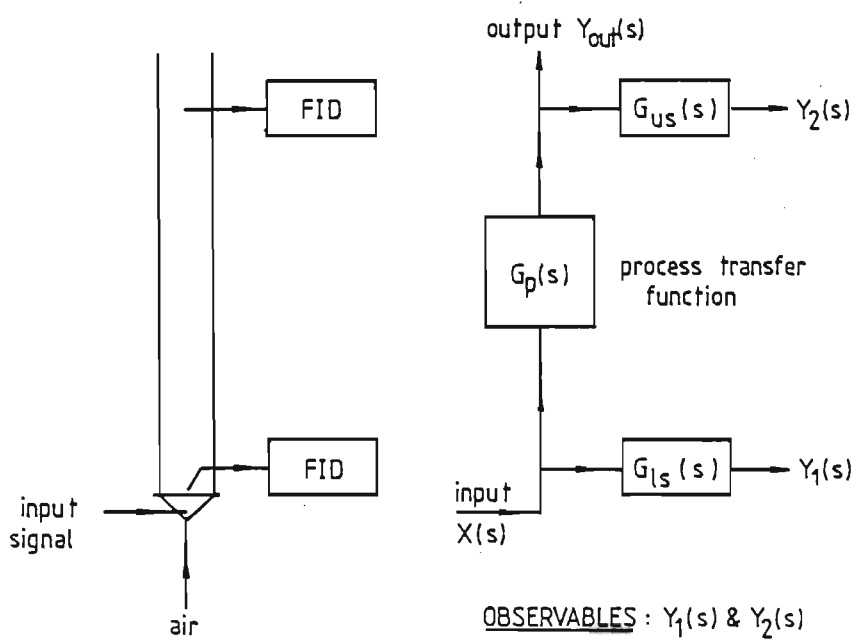

FIGURE 5.6   SAMPLING   CONFIGURATION

the resolution of $G_p(s)$. In order to achieve this, the gas sampling lines were designed to minimise time-lag and signal dispersion. These lines were made as short and obstruction-free as possible, containing one-eighth inch valves for flow control only. A minimum length of about 0.4 m was dictated by the geometry of the beds and the FID units themselves, and one-sixteenth inch tubing with an ID of 0.51 mm was used.

The sample lines were flared at the sample points, and short pipe-cleaners were inserted to keep the lines and FID units free of solids. Suction velocities were dependent on the pressure in the bed, and were generally in the range 1.5-2.0 m/s.

The dynamics of the sampling system in both cases was accounted for by on-line calibration. A methane pulse point was introduced immediately adjacent to the sample suction point as shown in Figure 5.7. A differential pressure of about 60 kPa was allowed to build up across the solenoid valve, and the solenoid switch then opened and closed in rapid succession. The FID signal was recorded on a strip chart, and the dead and rise times read off. Repeated tests showed that the dead and rise times of the recorded signal were essentially independent of the solenoid pressure differential beyond about 5 kPa - it was concluded that the tracer signal appears at the sample point virtually the instant the solenoid is energised, and that the observed dead and rise time characteristics are essentially those of the sampling system alone.
FIGURE 5.7   METHANE PULSE POINT

5.2.3   Calibration and System Validation

The FID output voltage vs methane concentration characteris=
tics were tested by blending a constant, measured bleed of
methane into the air supply below the grid. Linear responses
were obtained for methane concentrations below about 1% (by
volume) over a fairly wide range of sample flows - this type
of test was repeated periodically to ensure that the operating
point remained in the linear response region.

Linearity in the tracer detection system greatly simplifies the
data capture sequence. The absolute magnitude of the response
of a linear system is of no consequence as far as RTD studies
are concerned, and in this case the electronic signals could be
arbitrarily amplified or attenuated to acceptable levels for
recording.

The tracer detection system and the sample line calibration
procedure was tested by measuring impulse transmission velocities
in an empty tube. The hardware configuration is shown in
Figure 5.8, and the procedure involved first calibrating both
sample lines in terms of dead and rise times as discussed
previously. The lower solenoid was then opened and closed rapidly,
and the relay configured to switch the chart recorder on the
instant the solenoid was energised. The peak-to-peak transmission
time t_{pp} was read off the chart trace as shown, and a transmission
velocity computed by dividing the vertical separation by the
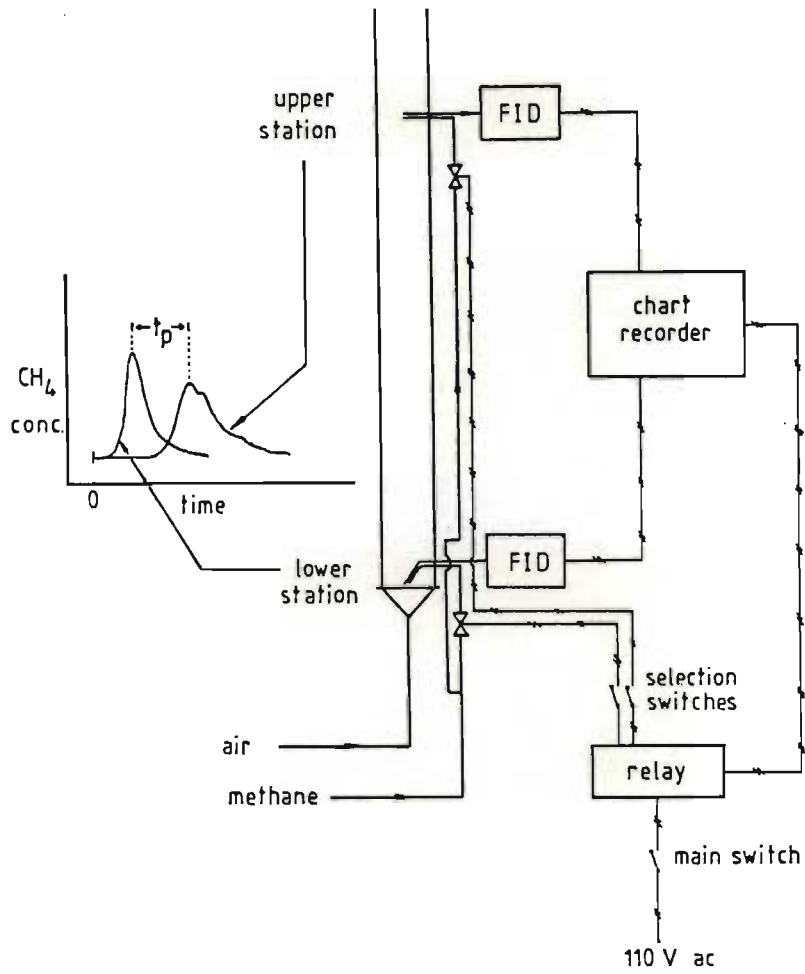

FIGURE 5.8   IMPULSE TRANSMISSION-TIME CONFIGURATION

corrected transmission time. This corrected transmission time was calculated as follows:

$$\Delta t_{pp}(corr) = \Delta t_{pp}(uncorr) + \left[(t_d + t_r)_{lower} - (t_d + t_r)_{upper} \right] \quad (5.4)$$

$$\text{station} \qquad \text{station}$$

where the subscripts d and r refer to dead and rise times respectively. The results of a series of such transmission velocity tests are shown in Figure 5.9. A radial profile effect in the empty 0.14 m tube is evident - this is not surprising, since the flow regime is transitional between laminar and turbulent over the range of superficial velocities covered. In any event, it is clear that the calibration and data interpretation procedures are essentially correct in that no significant time-lags remain unaccounted for.

5.2.4   Choice of a Tracer Testing Technique

Preliminary experiments in beds containing the iron oxide powder revealed the presence of significant process noise: a typical response to an impulse supplied below the grid is shown in Figure 5.10. The RTD function as measured here is clearly stochastic in nature; the noise is probably a result of bubble motion and associated pressure fluctuations as reflected in gas flow to the FID units. Single impulse and step-change tests would probably be of little direct use, and the alternative is to employ a statistical technique for RTD estimation. An averaged
FIGURE 5.9   PULSE TRANSMISSION VELOCITY

tube size   0.05 m
gas velocity 0.43 m/s
test section 0.97 m
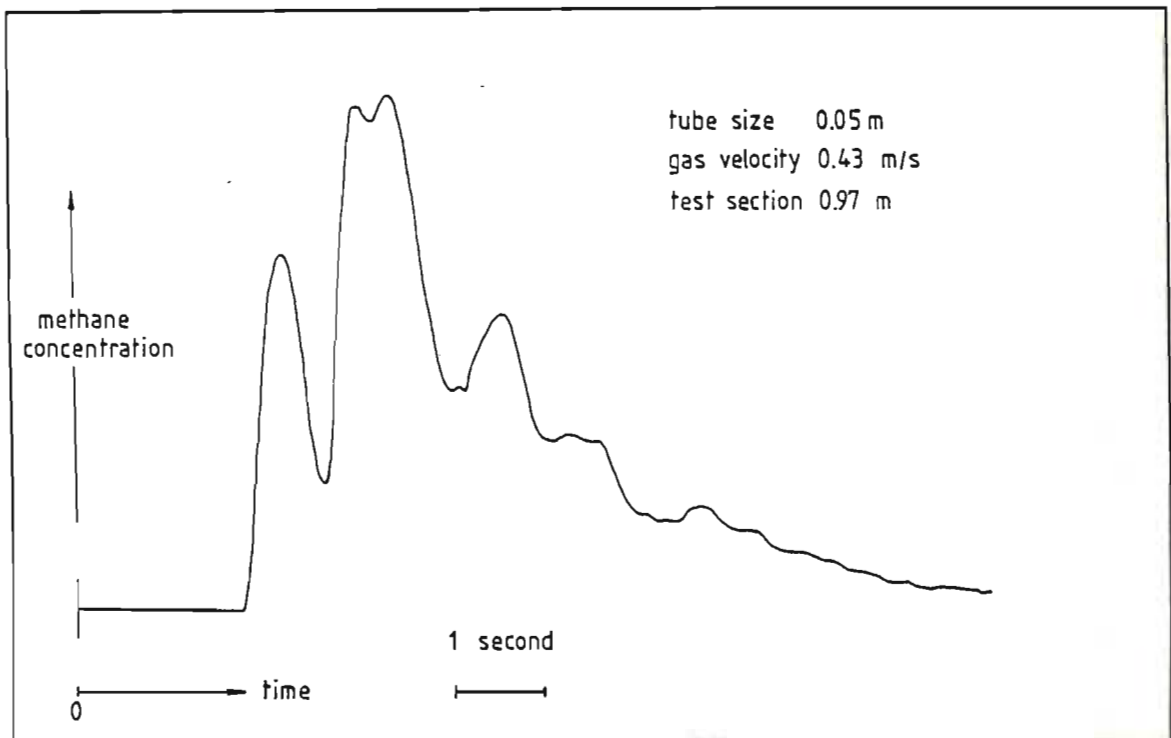

FIGURE 5.10   A TYPICAL NOISE-CORRUPTED IMPULSE RESPONSE

residence time function is required for comparison with model predictions, and noise removal should be inherent in whatever technique is applied.

A correlation technique was selected. This method consists of exciting the system with a random test signal, and forming the crosscorrelation function between the two observed signals. The autocorrelation of the lower sample station signal is also formed, and the two correlation functions are processed to the form of a system frequency response.

Consider a stationary random variable $Y_1(t)$. The autocorrelation function $r_{Y_1 Y_1}(\tau)$ characterises the dependence of $Y_1(t)$ on $Y_1(t+\tau)$, and may be written:

$$r_{Y_1 Y_1}(\tau) = \mathcal{E} \{Y_1(t)\ Y_1(t+\tau)\} \tag{5.5}$$

where $\mathcal{E}$ denotes ensemble expectation. The autocorrelation may be estimated from a sampled data time record as follows:

$$R_{Y_1 Y_1}(\tau) = \frac{1}{n} \sum_{k=1}^{n} \{Y_1(t_k)\ Y_1(t_k + \tau)\} \tag{5.6}$$

Similarly, the dependence of $Y_1(t)$ on $Y_2(t+\tau)$ may be estimated from:

$$R_{Y_1 Y_2}(\tau) = \frac{1}{n} \sum_{k=1}^{n} \{Y_1(t_k)\ Y_2(t_k + \tau)\} \tag{5.7}$$

A sufficient condition for equations (5.6) and (5.7) to yield unbiased estimates of their ensemble expectation values is that both Y_1 and Y_2 must be ergodic (99). Fourier trans= formation of the time-averaged estimates of the correlation functions gives estimates of the ensemble spectral densities:

$$S_{Y_1 Y_1}(jw) = \int_{-\infty}^{\infty} e^{-jw\tau} R_{Y_1 Y_1}(\tau) \, d\tau \tag{5.8}$$

$$S_{Y_1 Y_2}(jw) = \int_{-\infty}^{\infty} e^{-jw\tau} R_{Y_1 Y_2}(\tau) \, d\tau \tag{5.9}$$

Division of equation (5.9) by (5.8) yields an estimate of the process transfer function. The effect of time-lags in the sampling systems may be accounted for by shifting τ in equation (5.7) by an appropriate amount prior to the application of equation (5.9). The tacit assumption here is that rise time differences may be accounted for by small additional time shifts in equation (5.7) - a reasonable assumption in view of the fact that rise time differences are typically less than 10% of the corresponding dead time differences for the system employed here.

The exciting function for the generation of noise-corrupted time records (from which the correlation functions may be estimated) may take several forms. These include white noise, bandwidth limited white noise, random telegraph signals, random binary sequences and sinusoidal inputs. The last of these excites a single frequency only, and is considered impractical since

repeated experiments are called for. The other signal forms excite frequency ranges, but involve random processes which are extremely difficult to realise physically. From a practical point of view it is desirable to employ sequences which are only pseudorandom, but which have analytical autocorrelation functions. One such function is the pseudo random binary sequence or PRBS.

This function assumes one of two values with equal probability, and switchings take place at integral multiples of the decision time Δt_p. The signal is periodic, and the period is an integral number of decision times. A typical PRBS is shown in Figure 5.11. The autocorrelation function of such a PRBS is given by (105):

$$r(\tau) = \bar{a}^2(1 - \frac{N+1}{N} \frac{\tau}{\Delta t_p}) \quad \text{for } 0<|\tau|<\Delta t_p$$

$$\text{and} \quad r(\tau) = -a^2/N \qquad \text{elsewhere} \qquad (5.10)$$

Where N is the number of decisions in the sequence. For large N, this reduces to:

$$r(\tau) = \bar{a}^2(1 - \frac{\tau}{\Delta t_p}) \qquad 0<|\tau|<\Delta t_p$$

$$r(\tau) = 0 \qquad \text{elsewhere} \qquad (5.11)$$

The analytical form of the PRBS autocorrelation is not used directly in this study, since a signal introduced below the grid

PRBS signal

PRBS autocorrelation
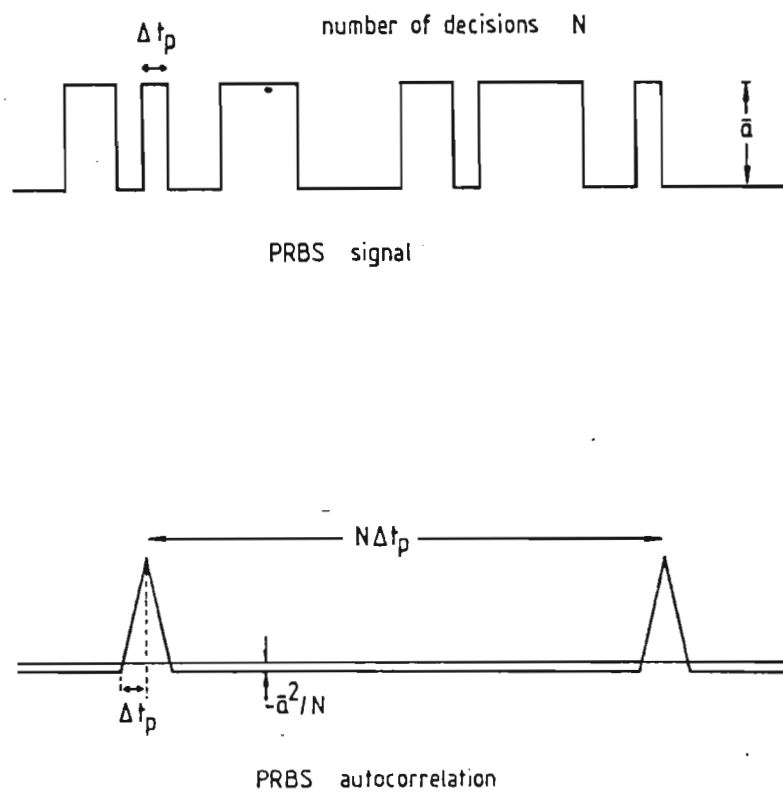

FIGURE 5.11   PRBS   CHARACTERISTICS

will necessarily be dispersed to some extent by the time it
emerges at the lower sample station. Nevertheless, the
autocorrelation observed at this point could be compared to
equations (5.10) or (5.11), and any gross errors in the
processing sequence should show up. The analytical auto=
correlation thus provides a useful cross-check on the data
capture and processing sequences.

5.2.5   Realisation of the Auto- and Crosscorrelations

In order to realise the correlation functions via equations
(5.6) and (5.7), one needs to specify the sampling interval and
the total number of data points per channel. The principal
constraint on the former is that of folding or aliasing. If
process frequencies greater than half the sampling frequency
are in evidence, the danger exists that information at these
frequencies may be folded back into and confused with information
at lower frequencies. The maximum frequency at which information
may be obtained, termed the folding of Nyquist frequency, is given
by:

$$\omega_{max} \quad = \quad \pi/\Delta t_s \qquad\qquad\qquad (5.12)$$

where Δt_s is the sampling interval. Common practice is to set
the sampling interval as small as possible (within practical
limits). In this study, the highest process frequencies of
interest were expected to be of the order of 4 radians per second.
A sampling interval of 0.1 seconds was selected, giving a Nyquist
frequency of about 31.4 radians per second.

The precision of the correlation function estimates is strongly dependent on the number of data points per channel employed. This is borne out by the results of Gallier et. al. (106), in which it is demonstrated that increasing the number of points from 930 to 5180 leads to a substantial improvement in the transfer function estimate. Woodburn, King and Everson (107) in fact showed that the standard deviation of errors associated with autocorrelation functions bears an inverse relationship to the number of readings (for their system at least). The improvement was found to be dramatic in the region 0-2000 points, and somewhat less so beyond 2000.

In this study it was decided to fix the number of points per channel at 5000. With a sampling interval of 0.1 seconds this gives a real-time record length of about 8.33 minutes, and any particular run therefore represents an RTD function averaged over this period.

Physical realisation was achieved by recording a time sequence on magnetic tape and processing the data off-line. The recording machine was a Philips ANA-LOG 7 unit operating in a frequency modulation mode, and during playback the tape speed was slowed by a factor of four. The computations were performed on an Apple II microcomputer based on an MCS 6502 microprocessor. The interface between the microcomputer and the tape recorder was an Interactive Structures AI 13 (12-bit)

A/D converter, sampling at 0.4 second intervals while playback
was in progress.

The program for the evaluation of the correlation functions
was written in the Apple version of BASIC, and a listing is
given in Appendix E. The functional forms of equations (5.6)
and (5.7) are also included.

5.2.6   Realisation of the PRBS Signal

There are at least two known ways of generating a PRBS signal.
One is based on Gaussian number theory and makes use of
quadratic residues (108,109). The other is based on the
properties of digital filters and their maximum length null
sequences (105), and makes use of a shift register circuit.
The latter is employed here.

Consider a bit shift register circuit configured as shown
in Figure 5.12.   The $\oplus$ denotes modulo-2 addition so that the
system variables only assume values of 0 or 1.   The symbol $\bar{D}$
denotes a delay operator.   The circuit is driven by a constant
frequency clock, and with each shift the contents of one register
is passed on to the next.   The truth table for modulo-2 addition
is:

$\oplus$	0	1
0	0	1
1	1	0
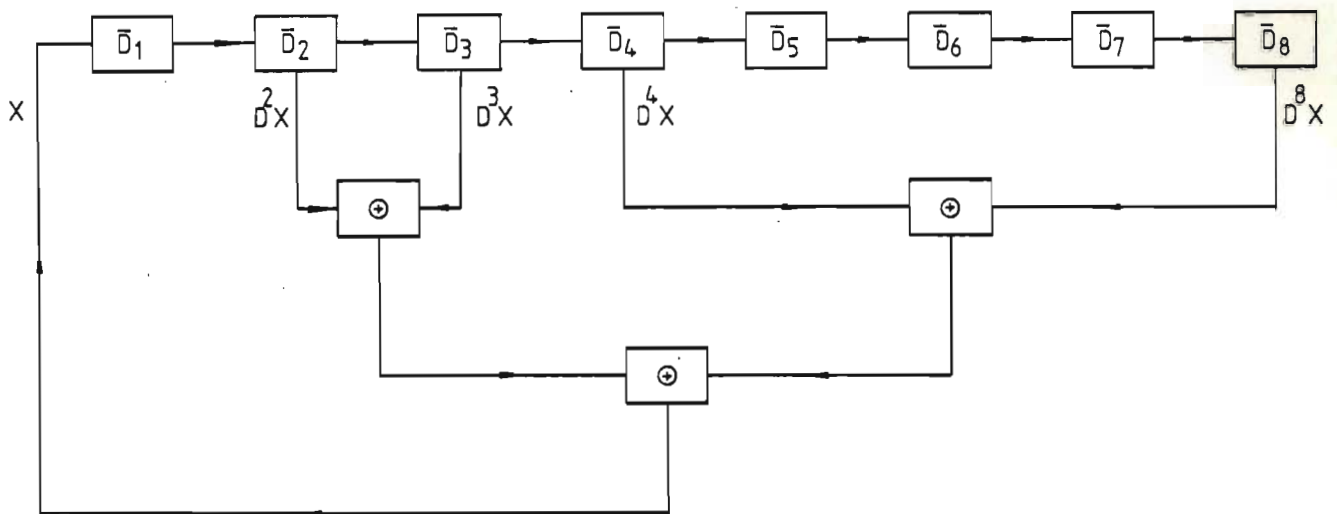

FIGURE 5.12   PRBS GENERATOR CIRCUIT

The characteristic polynomial governing the operation of this circuit is:

$$(1 \oplus \bar{D}^2 \oplus \bar{D}^3 \oplus \bar{D}^4 \oplus \bar{D}^8)X = 0 \qquad (5.13)$$

This polynomial has no factors and is itself not a factor of $(D^k \oplus 1)$ for $k < 2^8 - 1$. In other words, the characteristic polynomial is primitive, modulo 2 and will generate its maximum length null sequence if the starting condition is non-zero. The period of the sequence is given by $2^{np} - 1$ in general, where np is the order of the polynomial. In this instance a 255-decision PRBS is generated.

The circuit was constructed as shown in Figure 5.12, with an adjustable speed clock. A solid-state relay was operated off shift register number 8, and this relay in turn governed the operation of a solenoid valve feeding methane into the plenum chamber of whichever column was in operation. A pressure reservoir was included on the high pressure side of the solenoid, and bottled methane was fed to this reservoir via a hand-controlled needle valve. During a PRBS run the pressure in the reservoir was kept as constant as possible.

Three quantities related to the generation of a PRBS test signal need to be specified. These are the signal amplitude, the decision time and the number of decisions in the sequence. All

of these quantities should be chosen to maximise the
resolution of the system transfer function.

5.2.6.1 Amplitude

The theoretical optimum for the amplitude of the PRBS signal
is the maximum within the constraints imposed by linearity
considerations. In this study it was evident that the amplitude
of the test signal had very little effect on the results over a
fairly wide range. This is mainly due to the fact that the FID
units were extremely sensitive to low concentrations of methane.
These detectors could be operated with different potentials
across the electrodes, and the result was excellent resolution
over a wide range of tracer concentrations (below about 1% by
volume). In practice the PRBS amplitude was fixed at levels
dictated by the geometry of the feed lines and the available
pressure drop across the solenoid. The detector sensitivity
rather than the PRBS amplitude was varied to achieve suitable
signal strengths.

5.2.6.2 Decision Interval

Different criteria exist for selecting the PRBS decision time.
Himmelblau (99) suggests that the decision time should be
specified in such a way as to ensure that the first zero in the
power spectral density function occurs at a frequency well above
those of interest. The power spectral density function of a

PRBS signal is given by:

$$S_{PRBS}(j\omega) = \bar{a}^2 \Delta t \left[\frac{N+1}{N}\right] \left[\frac{\sin \omega \Delta t/2}{\omega \Delta t/2}\right] \qquad (5.14)$$

This function has a recurring zero at $\omega \Delta t/2 = k\pi$, k an integer. By this criterion the decision time should be smaller than about 1.57 seconds if the maximum frequency of interest is 4 radians per second.

A somewhat different criterion is suggested by King and Woodburn (81), based on experimental design from an information theory approach. They suggest that, for first order linear systems, the optimum decision time should be 1.2 times the process time constant. However, for diffusive mixing in a packed tower Everson (110) found that the decision interval becomes an insensitive variable in an optimum testing strategy.

Neither of the above criteria is strictly applicable to the system employed here. The signal observed at the lower sample station is dispersed to some extent as mentioned previously, and there is no reason why its spectral density function should conform closely to equation (5.14). King and Woodburn's (111) criterion is also probably not applicable, since the process under investigation is not first order. It could be argued that the exact form of the exciting signal is of little consequence, since the crosscorrelation function is formed between two underlined observed signals. This line of

reasoning suggests that the decision time should be chosen in such a way that the PRBS frequency spectrum covers that of the process, but that the exact choice of decision interval is not critical.

A practical approach was used to resolve this question. For a fixed set of conditions, three experiments were carried out with decision time to lumped process time constant ratios of 0.74, 0.37 and 0.11. The data from these runs was processed to the form of a system frequency response, and the magnitude ratio components are shown in Figure 5.13. It is immediately apparent that the transfer function estimation procedure is insensitive to the choice of PRBS decision time in the range covered.

For the sake of uniformity, the PRBS decision interval was taken to be half the lumped process time constant.

5.1.6.3   <u>Number of Decisions in the Sequence</u>

Accepted practice appears to be to choose a PRBS period length to give a small deviation of the autocorrelation below the abscissa, i.e. to maximise the number of decisions in the sequence. However, if experimental and theoretical crosscorrelations are to be compared, it may be advantageous to employ a shorter decision sequence. King and Woodburn (111) suggested this, and Haines (112) deliberately used a short PRBS sequence.
FIGURE 5.13   SENSITIVITY OF G(jω) TO PRBS
DECISION TIME

In this study there is no clear incentive to reduce the PRBS period length, since the experimental data is compared to the model predictions in the frequency domain. It is not clear how correlation function deviations below the abscissa will show up in the process transfer function, and it was decided to maximise the PRBS period length. A 255 decision sequence was used as discussed previously.

5.2.7   Overall Data Capture and Processing Sequence

The preceeding sections discuss the selection and realisation of the various components of a data capture and processing system. This section describes the overall system and sequence of events in the recording and processing of a single run.

The entire operation is executed in three stages. The first of these is the actual recording of data, and this is followed by off-line correlation analysis. The third stage involves time shifting and Fourier transformation to frequency response form. ·

Figure 5.14 illustrates the data recording process. Gas velocity in the bed is set to the desired value, and the pressure drop across the filters is controlled in such a way as to provide a suitable pressure driving force for sampling. The valves in the FID sample lines are then adjusted if necessary, and the methane pulse-points are engaged to determine dead and rise times associated with the sampling systems. Pressure in the methane
FIGURE 5.14   DATA RECORDING SETUP

reservoir is then set to provide a suitable pressure drop
across the tracer injection solenoid, and the PRBS generator
is switched on. Tracer flows into the plenum chamber as
dictated by the PRBS signal, and the methane reservoir pressure
is maintained at its initial level by hand control. The lower
and upper station signals are monitored on the chart recorder,
and are amplified or attenuated to suitable levels for recording.
The tape recorder is then engaged, and a 10-minute time record
of each of the signals is captured in analogue form. On completion
of recording the PRBS generator is switched off, and the pulse-
points employed once again to check sampling system dynamics.
Average (before and after) dead and rise times are used in the
data processing.

The correlation analysis layout is shown in Figure 5.15. The
tape is played back at a reduced speed (a factor of four) into
a 12-bit A/D converter via a 15Hz low-pass filter. This filter
is included to eliminate high-frequency noise picked up during
recording, and the filtered signal is monitored on an oscilloscope.
The A/D converter samples at 0.4 second intervals as dictated by
the microcomputer, and 5000 readings from each channel are
stored in the memory of the latter. Once the digitisation and
collection of data has been completed the tape recorder is
switched off and correlation analysis commences. The microcomputer
engages the printer, and correlation function values for successive
time shift increments are printed as they are computed.
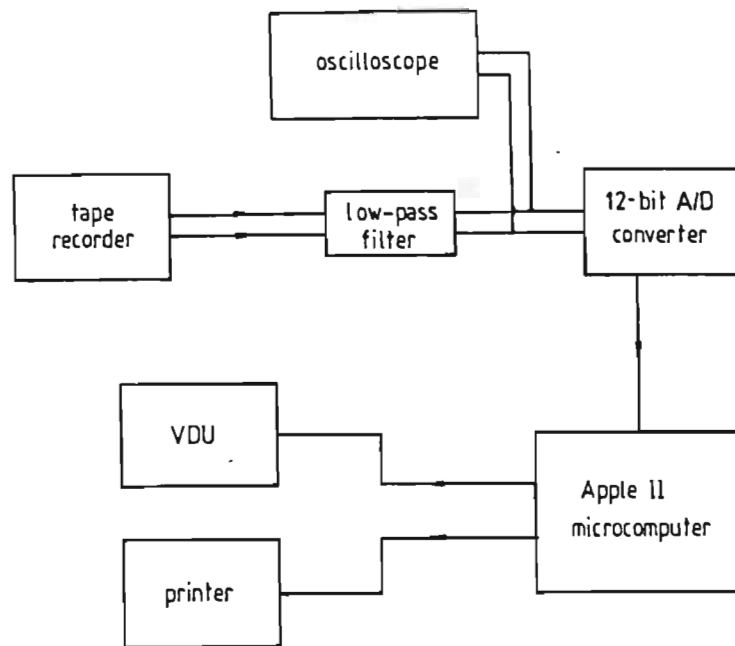

FIGURE 5.15   CORRELATION ANALYSIS CONFIGURATION

The time-lag shift and Fourier transform processes are
carried out in the main model fitting program. The auto- and
crosscorrelation functions are plotted by hand, and any obvious
bumps or discontinuities are removed by drawing a smooth curve
through the data. (This was in fact seldom necessary - the
correlation functions generally described smooth curves as
plotted). The correlation functions are then fed into the
main program as though they represent a conventional impulse-
response type of test. A time shift quantity calculated from the
differences in sampling system dead and rise times is included,
and the crosscorrelation is shifted relative to the input auto=
correlation by this amount before the Fourier transform routine
is called. Fourier transformation is then carried out as described
in Chapter 4, and the overall result is an experimental transfer
function against which model predictions may be optimised.

5.3 Parameter Reduction by Independent Measurement

The fluidised bed models described in Chapter 4 generate frequency
responses as functions of model parameters. In principle any number
of these parameters may be optimised by comparison with experimental
RTD data. However, the greater the number of optimised parameters,
the less the significance of any particular parameter value returned.
The number of parameters to be determined by model fitting should
clearly be held to a minimum to ensure maximum significance in those
that are in fact estimated in this manner.

5.3.1   Parameter Identification

The input quantities required by the seven models employed
in this study are listed in Table 5.1, and Table 5.2 identifies
the parameters to be optimised by simplex sequencial search in
each case.   The parameters in Table 5.2 will henceforth be
referred to as optimised parameters, and those appearing in
Table 5.1 but not in Table 5.2 as auxiliary parameters.

As regards the auxiliary parameters, the geometric parameters
in Table 5.1 and the superficial velocities are measured directly
and need be considered no further. Bubble velocities, the bubble
phase dispersion coefficient, dense phase voidage and velocity,
bubble holdup and the ratio of cloud to bubble volume need to
be estimated independently in some suitable manner.

5.3.2 Auxiliary Parameter Estimation

5.3.2.1 Bubble Velocity and Axial Dispersion Coefficient

Bubble velocity U_b was measured by injecting a pulse of methane
into the bed at the lower sample station and measuring the time
lag preceeding the emergence of the first local tracer peak at
the upper station. After correction for sampling system dead and
rise times (as for the set-up shown in Figure 5.8), a "bubble"
transmission velocity was computed (104).

The technique described actually determines the transmission time
of a tracer-rich packet of gas through the bed, and from a modelling

TABLE 5.2   IDENTIFICATION OF PARAMETERS TO BE OPTIMISED

point of view it may be argued that this represents an appropriate bubble velocity. This technique does not distinguish between single bubbles and groups of bubbles undergoing coalescence and/or splitting, and this is certainly consistent with the type of model employed which recognises only a bubble phase and not individual bubbles.

Bubble velocity is inherently a stochastic quantity, and this calls for replicate experiments - some 40 to 60 individual bubble velocities were measured for each set of conditions. An average based on arithmatic mean transmission time was computed for use in conjunction with all but the MBT model, while for the latter, these data were drawn up in the form of a histogram describing five velocities (u_i's) and associated relative abundances (f_i's). The axial dispersion coefficient in the bubble phase D_b was inferred from the standard deviation of transmission times as follows:

$$(\frac{D_b}{U_b L_t}) = \frac{1}{2} (\frac{\text{standard deviation}}{\text{mean transmission time}})^2 \qquad (5.15)$$

This expression is consistent with a one-phase axial dispersion model (for small amounts of dispersion) as assumed by the BPD model for the bubble phase.

The estimation of other auxiliary parameters and indeed the entire modelling procedure, depends heavily on bubble velocities thus determined, and in the light of this it was considered necessary to validate the procedure before proceeding. This validation consisted of measuring slug velocities in the small tube with 71 micron FCC

catalyst and ensuring that only fully established slug flow was present in the test section. The lower sample station was shifted to a point about 1 m above the distributor and the upper station located at a distance of 1.5 m above this. "Slug" velocities were then measured by the technique described, and compared with the appropriate literature expressions which are known to describe this system satisfactorily (74). The results of this comparison are shown in Figure 5.16, and from these data it appears that the technique gives results which are consistent with those obtained by other methods.

slug velocity (m/s)

superficial velocity (m/s)
FIGURE 5.16   SLUG VELOCITIES IN AN FCC POWDER

The technique used here for measuring bubble velocities is not a
conventional one, and its interpretation is likely to be a subject
for debate. The success of the validation procedure under slug
flow conditions allows some degree of confidence, though it might
be suggested that what the probe sees in the larger bed is not
representative of the bed as a whole: this applies to both the
bubble velocity and RTD measurements, and is discussed in some
detail in section 5.4. In defence of this procedure, it should be
pointed out that the transmission velocity of gas in the lean phase
is a fundamental parameter of the models employed, and this
procedure aims at a direct measurement. There is no reason to
suppose that an alternative measurement based on individual
bubble observations (e.g. X-rays or local bubble probes) would yield
a result any more appropriate, since as stated previously, the
models employed here do not recognise individual bubbles.

It should be clearly stated that the assumption that this technique
yields an appropriate bubble velocity for modelling purposes is
fundamental to all the results quoted in this investigation. If
this facet of the work is to be questioned, then the overall results
are to be regarded as being subject to this limitation. However, it
should also be noted that since all the models and both fluidised
beds are treated in the same way the comparative aspect of the work,
which is where its main strength lies in any event, is not in
question.

5.3.2.2 Dense Phase Voidage and Velocity

The flow interruption or bed collapse technique as originally

suggested by Rietema (113) was employed. The method involves

rapidly cutting off the air supply, and plotting the bed height

as it settles. Bubbles leave the bed in the first few seconds

or so after the gas supply has been closed off, and thereafter the

dense phase collapses slowly as interstitial gas escapes. This

(steady) collapse may be extrapolated back to the time of flow

interruption to yield the height of the dense phase alone in the

bubbling bed, and the voidage in this phase may be computed

directly from the material balance expression:

$$\varepsilon_d = 1 - \frac{W}{A_t H_d \rho_p} \qquad (5.16)$$

The dense phase velocity U_d may be inferred from the slope of the

steady collapse portion of the height vs time curve. This

quantity is dependent on the geometry of the system as demonstrated

by Abrahamsen and Geldart (114), and the correction applied is

described in detail in the author's Master's thesis (104).

It is recognised that the dense phase velocity as measured by this

technique is essentially equivalent to the gas-solids slip velocity

in the dense phase. Solids circulation is recognised by the CCBM

model, i.e. solids ascend at more or less bubble rise velocity in

the cloud-wake phase and descend (more slowly) in the emulsion phase.

For the very fine powder used here and the low associated dense

phase slip velocity (around 0.008 m/s), it is possible that down-

flowing solids could entrain gas and cause it to move downwards relative to the vessel wall (in the emulsion phase).

In order to meet the input requirements of the CCBM model it was considered necessary to measure the effective downflow velocity of gas in the emulsion. The technique employed is essentially the same as that used to determine bubble velocities: a pulse of methane was once again introduced into the bed, but this time the gas sampling was performed *below* rather than above the injection point. The downflowing emulsion solids entrained some of this tracer gas and generated a series of local peaks at the lower probe, the first of these appearing after a delay corresponding to some characteristic transmission time. This was interpreted as a mean gas velocity in the emulsion phase, and is subject to the same constraints as the measured bubble velocities. Validation was somewhat less satisfactory in this case but was nevertheless performed by timing the solids movement between two marks on the wall of the 0.05 m column with a stopwatch. After correction for the dense phase velocity according to the expression:

$$U_e = \frac{U_d}{\varepsilon_d} - U_s \qquad (5.17)$$

where U_s is the solids velocity and U_e the gas velocity in the emulsion relative to the vessel wall, it was found that the two measurements agreed to within ca 20%. The error was found not to show any consistency in terms of sign and therefore did not suggest

any systematic deviation, and was considered to be generated more
by the stopwatch timing procedure than the tracer gas technique.
The tracer technique for measuring emulsion velocities was accepted
on this basis.

5.3.2.3   Bubble Holdup

The bubble holdup could be determined in two ways. The first of
these is the bed collapse technique (104) - the difference between
the height of the dense phase and that of the bubbling bed corresponds
to the volume of gas in the bubble phase. The main problem with this
approach is the fact that the height of a bubbling bed is poorly
defined. The procedure is strongly sensitive to the exact choice of
bed height, particularly at low superficial velocities.

The second technique employs a gas division model. Continuity
considerations demand that, for a fine powder system:

$$U_b \delta = U_o - (1-\delta) U_d \qquad (5.18)$$

for a two-phase model, and

$$U_b \delta = U_o - (1-\delta-\alpha\delta) U_d \qquad (5.19)$$

for a three-phase one (such as the CCBM model). Equation (5.18)

may be solved for δ in terms of U_o, U_d and U_b and the former

calculated directly, since the latter quantities are known. The

stochastic quality inherent in δ is carried in U_b, and a suitably

averaged bubble velocity is expected to yield an appropriately

averaged bubble holdup. Equation (5.19) may be solved for δ in

the same way, the only difference being the presence of the α

term. The estimation of this quantity is described in the next

section, and δ may once again be computed directly.

Of the two methods available for estimating δ, the second is

preferable in the opinion of the author. It is this technique

that is employed in this study.

5.3.2.4   Ratio of Cloud to Bubble Volume

The CCBM model is based on a solids circulation pattern: solids

travel upwards in the clouds and wakes and downwards in the emulsion

phase. The cloud and wake phases are usually lumped together, and

according to this model solids continuity requires that (28):

$$\alpha\delta\, U_b = (1-\delta - \alpha\delta)\, U_s \qquad (5.20)$$

where U_s is the solids velocity relative to the vessel wall in the

emulsion phase. This expression may be solved for α to yield:

$$\alpha = [\frac{1-\delta}{\delta}] \; \frac{U_s}{U_b + U_s} \qquad\qquad (5.21)$$

Now U_b is measured directly, and U_s may be obtained from U_e and U_d measurements (equation (5.17)). To evaluate α using equation (5.21) therefore requires one additional quantity: an independent estimate of δ. An examination of the magnitudes of the numbers involved in this study, however, suggested that to a first approximation at least, δ could be replaced by U_o/U_b. This effectively involved neglecting $(1-\delta)U_d$ or $(1-\delta-\alpha\delta)U_d$ in favour of U_o in equations (5.18) and (5.19) respectively, an assumption which does not appear to be too disturbing in this situation since U_d was constant at around 0.008 m/s and U_o varied from about 0.15 to 0.7 m/s. The maximum error expected in δ from this simplification is therefore around 4% - this was considered to be well within experimental error, and α was evaluated from

$$\alpha = [\frac{U_b - U_o}{U_o}] \; \frac{U_s}{U_b + U_s} \qquad\qquad (5.22)$$

No explicit validation of this procedure was attempted, mainly due to the fact that no direct measurement was possible within the constraints imposed on this investigation. Values of α thus computed were, however, checked against published values for reasonableness and found to be acceptable on this basis.

5.4   Overall Experimental Strategy

As stated previously, one of the aims of this investigation is to quantify the effects of vessel diameter and internal geometry on interphase mass transfer. The question of scale-up is implicit in the study of the diameter effect, while the investigation into the effect of coils and the presence or otherwise of the sparger is aimed at providing guidelines for the solution of problems on the demonstration reactor.

It is clear that tube size and internal configuration are not the only independent variables to be considered. The effect of bed height may be very significant, and some idea of the dependence on gas velocity could prove extremely useful. The cold model experimental programme accordingly considers the following independent variables:

    (i)   Gas velocity

   (ii)   Bed height

  (iii)   Tube size

   (iv)   Coils/no coils in the 0.64 m unit

    (v)   Sparger/no sparger in the 0.64 m unit.

The following strategy was decided on: at any particular combination of bed height and vessel geometry, a number of runs at different superficial velocities would be carried out. For

any particular vessel geometry, runs at different bed heights would be executed. Four geometric configurations are considered, and these are identified in Table 5.3.

Varying system geometry and gas velocity (within the limits of the supply and metering system) presents no problem. However, the same is not true for varying the bed height. There are two ways in which this may be performed: the first is to establish a deep bed, and to operate the gas tracer system over different heights within this bed. The second is to vary the powder charge, and to operate the tracer system over the whole bed in each case. An additional question associated with the latter is where to locate the upper sample station - average bed height, below minimum bed height or in the freeboard?

TUBE DIAMETER	INTERNAL GEOMETRY	EFFECTS COVERED
0.05 m	porous plate	U_o, L_f
0.64 m	coils	U_o, L_f
	no coils	U_o, L_f
	coils, sparger	U_o, L_f

TABLE 5.3   COLD MODEL GEOMETRIC CONFIGURATIONS

It is clear that the two strategies for varying L_f should yield different results. Lateral gradients are expected in the larger bed, and the results from gas sampling with a single probe at some intermediate axial position would probably depend on radial probe location. If a single probe is to be employed, it is imperative that sampling be carried out where the radial gradients are at a minimum. At first glance the appropriate location for the upper probe would appear to be the disengaging region, since appreciable lateral mixing is observed in this area. However, this would necessarily mean that a crossflow enhancement effect of the type reported by Miyauchi et al. (93), if present, would be reflected in the results. This in turn implies that any axial profile determined by operating with different powder charges would be distorted, since a shallow bed would contain a (disengaging) crossflow enhancement not present at the same axial location in a deeper bed. A further objection to locating the sample probe in the disengaging region is the fact that the gas holdup in this zone is poorly defined, and the assumption that the probe draws gas from bubbles and the dense phase in proportion to the presence of these phases in the system no longer holds.

In the light of this it was decided that the upper sample probe would be located immediately below minimum expanded bed height. This allows maximum advantage to be taken of the lateral mixing process in the disengaging region whilst avoiding the deleterious effects discussed above. The time-averaged nature of both the RTD and the bubble velocity measurements would ensure that maximum

radial averaging would be implicit in the results. It was also decided that the upper sample probe would be located radially at a point midway between the wall and the centreline of the vessel.

CHAPTER   6

RESULTS AND DISCUSSION

This chapter is presented in five sections. The first deals
with auxiliary system parameters, and the second describes
general features of the RTD data and the model fitting. The
third section is devoted to the actual model screening, and the
fourth covers crossflows and the effects of vessel geometry.
In the fifth section the axial crossflow profile is examined
in terms of bubble to dense phase interfacial areas.

6.1   Auxiliary System Parameters

6.1.1   Bubble Velocity and Axial Dispersion

6.1.1.1   0.05 m Unit

Slug velocities measured at three different bed heights are
shown in Figure 6.1. There is no apparent dependence of U_s on
axial probe location, and the results are adequately described by:

$$U_s = 1.15 (U_o - U_d) + 0.63 \sqrt{g D_t} \qquad (6.1)$$

The excess velocity coefficient (1.15) is probably a velocity
profile effect, and is close to the 1.2 reported by Nicklin et. al.
(71) for an air-water system. The slug rise coefficient (0.63),
however, exceeds the commonly accepted values of 0.35 and 0.35 $\sqrt{2}$
(73, 74) by factors of about 1.8 and 1.3 respectively. This
FIGURE 6.1   SLUG VELOCITIES   ON THE 0.05 m UNIT

suggests that slugs in this system experience a smaller

retarding force than those in systems involving coarser particles.

The high dense phase voidages observed for this type of system (104)

are probably consistent with low dense phase viscosities, and this

could in turn be responsible for the high slug rise coefficient.

It should also be noted that slug rise coefficients of the

magnitude reported here are by no means unique to this study-

data reported by Tsutsui and Miyauchi (115) for example, suggests

a coefficient as high as 0.86 for a fine FCC powder.

Axial dispersion coefficient data for the bubble phase, as

inferred from the spread in velocities (by applying equation

5.15), is given in Figure 6.2. Despite the large amount of

scatter, it is clear that a deeper bed is associated with a larger

dispersion coefficient. The scatter is probably a result of the

rather small sample size - 40 to 60 observations per set of

conditions is, in all likelihood, too small a number for obtaining

a good estimate of the ensemble standard deviation. A few hundred

observations might well be required for a significantly better

estimate: the general techniques employed by Rowe (64), for

example, involve very large numbers of individual bubble observations.

The small sample size was employed in this study for practical

reasons. Experiments with larger numbers of observations were

considered unjustified, since errors possibly introduced into the

modelling routines from this source were considered small relative

to those inherent in the overall procedure.
FIGURE 6.2   BUBBLE PHASE DISPERSION COEFFICIENTS
IN THE 0.05m UNIT

6.1.1.2 0.64 m Unit : No Sparger

Bubble velocities measured at four different axial positions in the 0.64 m unit (with coils - hydraulic diameter 0.19 m) are given in Figure 6.3. The most striking feature is the strong axial velocity profile : it appears that bubbles rise at a moderate rate in the lower regions of the bed and accelerate progressively higher up. The data as presented represents average velocity in the test section. However, a local velocity profile at fixed superficial velocity may be inferred if a particular form of height dependence is assumed. One possibility is:

$$U_b = a + b.\exp(cz) \qquad (6.2)$$

where a, b and c are constants and z is axial position. The integrated or height-averaged form of equation (6.2) may be compared with data from Figure 6.3, and the constants adjusted for minimum error by the simplex technique. At a superficial velocity of 0.3 m/s, this procedure leads to:

$$U_b = 3.24 - 2.38 \exp(-0.32z) \qquad (6.3)$$

where U_b and z are in m/s and m respectively. This expression is plotted in Figure 6.4, and suggests that bubbles rise at velocities exceeding 2 m/s beyond about 2 m above the grid. It also suggests that these velocities approach a limit of about 3.2 m/s, though this could simply be a result of the form of the equation.
FIGURE 6.3   BUBBLE VELOCITIES IN THE 0.64 m UNIT
FIGURE 6.4   LOCAL BUBBLE VELOCITY PROFILE

Application of the well-known Davidson and Harrison (39)
bubble rise expression (solved for d_b) to the local velocity
profile yields the bubble diameter profile shown in Figure 6.4.
It is clear that these diameters are not physically plausible,
particularly when it is noted that the bed contained immersed
coils giving a maximum free span of about 0.15 m only. These
diameters only appear reasonable when the bubble rise coefficient
is increased from 0.71 to about 1.5-1.6: this suggests a strong,
inherent increase in this parameter over accepted literature
values, possibly associated with a high dense phase voidage and
a low dense phase viscosity. An equally plausible explanation
is the existance of bubble chains and preferred bubble tracks of
the type observed by Werther (53). He in fact modelled the
chain phenomenon by allowing the bubble rise coefficient to
increase with tube size, and suggested an upper limit of 1.6 for
beds of 1 m or more in diameter. It is not possible, on the basis of
the information given, to establish which of these effects more
correctly explains the high velocities. It should be noted,
however, that the difference is irrelevant as far as the overall
modelling procedures are concerned since, as stated previously, the
models do not recognise individual bubbles.

In the case where the coils were removed from the bed the
bubble velocity profile changed somewhat relative to that in
the coil-containing system. Bubble velocity data for the coil-
free bed is shown in Figure 6.5, along with the trajectory for
the same test section height from Figure 6.3. The coil-free
system allows higher bubble transmission velocities in the

test section : 3.05 m

gas velocity (m/s)
FIGURE 6.5   BUBBLE VELOCITIES   IN THE 0.64 m UNIT
(NO   COILS)

superficial velocity region 0.1-0.3 m/s, and the profiles
appear to converge at velocities in excess of 0.4 m/s. This
behaviour could possibly be explained in terms of the inhibiting
effect of coils on bubble growth: horizontal baffles are
thought (116) to limit bubble size, and a similar but weaker
effect could be operating here. It is also possible that coils
somehow promote the formation of a relatively larger number of
preferred bubble tracks, thus acting as a kind of distributor
in the bed. Bubble chains might be expected to rise faster if
they consist of relatively more bubbles and rise in relatively
fewer tracks. In any event, it appears from this data that the
presence of coils enhances bubble to dense phase contact times.

Bubble phase axial dispersion coefficients are given in
Figure 6.6. The absolute magnitude of this parameter is sig=
nificantly greater than was the case in the slugging bed, and
in the 0.64 m coil-free system, dispersion coefficients are high
relative to those in the coil-containing bed. In the latter the
bed height dependence appears similar to that observed in the
0.05 m tube, though the large amount of scatter obscures any
clear trends.

A large axial dispersion parameter in the coil-free bed relative
to that in the coil-containing one could be explained as follows:
at any instant in the coil-free system, the bubbles could
conceivably exist in the form of a few high-speed bubble chains
FIGURE 6.6   BUBBLE PHASE DISPERSION COEFFIENTS
IN THE 0.64 m UNIT

superimposed on an otherwise randomly distributed population.
The velocity difference between the chains and the randomly
distributed component could be fairly high, and so too dispersion
on a global scale. The introduction of coils into the bed could
have the effect of distributing the bubble tracks more evenly
as mentioned previously, and this could in turn shorten the
length or period of existence of individual chains. The velocity
difference between chains and randomly distributed bubbles would
accordingly be reduced, and lower dispersion coefficients would
be obeserved.

6.1.1.3   0.64 m Unit : Sparger Case

Bubbles sparged into the bed some distance above the main gas
distributor might be expected to rise in a manner somehow
related to that of bubbles originating at the grid. The bed
above the sparger sees the some total volumetric gas flow in the
form of bubbles as would have been the case if all the fluidising
gas had been introduced via the grid. However, in this instance
bubbles enter the region above the sparger as a mixture of
presumably large (grid) and small (sparger) bubbles. Only the
sparger bubbles are "tagged" with tracer, since it is the history
of these that could dominate performance in the situation where
some limiting reactant is sparged into a fluidised bed.

Measured rise velocities of bubbles introduced via the sparger
are shown in Figure 6.7. The system was operated as follows:
FIGURE 6.7   SPARGER CASE   BUBBLE VELOCITIES

one third of the fluidising air was fed to the sparger, and

the rest to the grid. Tracer was injected at one of the

sparger nozzles, and bubble transmission velocities measured in

the region between the sparger and the upper sample station.

From the data in Figure 6.7 it is clear that, relative to the

bubble velocity trajectory shown in Figure 6.3 for the sparger-

free system, the local axial velocity profile (at U_o = 0.3 m/s)

is flat in the lower regions of the bed and increases sharply

higher up. It appears, in fact, that bubbles from the sparger

retain their smaller size and lower rise velocity to a distance of

about 1.5 m above the level of their introduction into the bed.

By about 2.7 m above the sparger, however, it would seem that

these bubbles have either grown to a size and velocity similar to

that of the grid bubbles, or participated in the formation of

chains of bubbles of mixed origin. A clearer explanation of the

axial velocity profile of sparger bubbles would do much to aid

general understanding of this type of system, but it must be

conceded that the data in Figure 6.7 is insufficient to support

further speculation.

6.1.2   Dense Phase Parameters

6.1.2.1   Dense Phase Voidage and Velocity

In a previous study (104) it is shown that dense phase voidage

is insensitive to gas velocity in 0.05 and 0.14 m tubes, and that

measurements in these tubes agree. In the 0.64 m tube, on the

other hand, it is demonstrated that ε_d as measured by the bed

collapse technique is apparently lower and increases (toward

the smaller tube value) with increasing gas velocity. This

type of behaviour could be a result of the presence of partially

defluidised material in the bed, but could equally well be a

result of the application of the bed collapse technique to too

large a unit. Uniform slumping is more difficult to achieve in

a large vessel, and preferential slumping of certain sections of

the bed could conceivably give rise to misleading results.

Dense phase voidage was measured in the 0.05 m unit and confirmed

on a 0.14 m tube. A value of ε_d = 0.622 was obtained. Anomalous

behaviour was observed in the 0.64 m unit, and it was decided that

the value obtained in the smaller units should be assumed applicable

to the large cold model. This assumption is consistent with

results obtained during the Shell Chlorine [117,118] scale-up study,

and is defensible in the light of uncertainties associated with the

application of the bed collapse technique. This assumption may also

be supported as follows: if regions of partially defluidised

material are in fact present and faithfully reflected by the bed

collapse technique, it seems unlikely that bubbles would be

exposed to this relatively low-voidage dense phase material to

any significant extent. Partially defluidised powder would, in

all probability, be found at the vessel walls and in the immediate

vicinity of the coils. Bubbles would tend to avoid such regions

by their very nature, and effectively be exposed to fully expanded

dense phase material only. The low dense phase voidage
measured by bed collapse experimentation in the large unit
would accordingly represent a poorer estimate of ε_d as seen by
the bubbles than that measured in the small unit.

The same overall reasoning applies to the dense phase velocity
U_d. A value of 0.0079 m/s was measured in the 0.05 m tube and
assumed applicable to the 0.64 m unit.

6.1.2.2 Downward Gas Drift Velocity

Downward gas drift velocities as measured by the tracer technique
in the 0.05 m tube are shown in Figure 6.8. The tracer method
worked reasonably well on this unit, and also performed satis=
factorily when tested on a 0.14 m tube. However, application to
the 0.64 m unit yielded no significant results: gross circulation
patterns and a general lack of radial uniformity confounded both
the measurement and the definition of a simple average downward
drift velocity. Velocities of the order of 0.5 m/s were in fact
measured, but these were probably not consistent with the definition
as required by the Kunii-Levenspiel (28) gas division model. In
order to satisfy the modelling requirements, the data in Figure 6.8
was assumed to apply throughout. A similar assumption was applied
to the ratio of cloud to bubble volume α, and the impact of both of
these assumptions on the modelling procedures is discussed in
section 6.1.3.
FIGURE 6.8   DOWNWARD DRIFT VELOCITY AND RATIO OF
CLOUD (PLUS WAKE) TO BUBBLE VOLUME

6.1.3   Ratio of Cloud to Bubble Volume

The ratio of cloud to bubble volume α as calculated on the basis of equation (5.22) is shown in Figure 6.8 for the 0.05 m unit. Since no downward gas drift velocities were successfully recorded on the larger unit, an assumption was called for in order to satisfy the CCBM modelling requirements. It was reasoned that due to the low dense phase velocity relative to the bubble rise velocity, the bulk of the cloud-wake phase would most likely be centred in the wakes of the bubbles. If this be true, then the bubble wake data of Rowe and Partridge (27) would form a reasonable basis for estimating α in the large unit. However, it was also noted that the values in Figure 6.8 are in fair agreement with the range of possible values quoted by Rowe (64), and that a trend of decreasing α with increasing gas velocity might indeed be expected as coalescence and possible wake shedding effects come into play. It was therefore decided that, since the values obtained on the small unit were consistent with published data and the trend with gas velocity was not unreasonable, these values should be assumed applicable to the larger unit.

The impact of this assumption as well as its counterpart related to the downward gas drift velocity on the overall modelling scheme is not great. The inherent danger is that the CCBM model may be unfairly discriminated against if these parameter values are inappropriate, though it is easy to check this by testing the sensitivity of the model. In the early stages of this investigation the CCBM model was in fact run with α as an additional parameter to

be optimised against the experimental RTD data, and it was found
that in the region of the optimum the sensitivity to changes in
α was very weak indeed. This is not at all surprising, though, in
view of the results quaoted in section 6.3.1 which suggest that the
cloud and emulsion phases should be considered lumped to form a
single dense phase. Though the model sensitivity to changes in
downward gas drift velocity was not explicitly tested in the same
way, the same remarks are assumed to apply.

6.2   General Characteristics of the RTD Data and Model Fitting

6.2.1   Experimental RTD Data

A time record of the kind of data that was obtained from the 0.64 m
bed is shown in Figure 6.9. PRBS excitation is discernable in the
signal from the lower sample station, though it is clear that some
tracer dispersion has occurred. This is a result of the fluidised
bed itself, as well as lags and dispersion processes in mainly the
sample lines and FID units. It should be pointed out, however,
that some sluggishness in the sampling system is not altogether
undesirable.

Increasing the sample gas flow to the detectors has the effect of
"sharpening up" the signal, but besides presenting possible linearity
problems, makes system more sensitive to pressure fluctuations
associated with bubble motion. The net result is a reduction in
the signal-to-noise ratio. It should also be noted that dispersion in
the sampling system is expected to impose a high-frequency limit on

185
FIGURE 6.9   TYPICAL NOISE-CORRUPTED TIME-RECORD

the range at which useful information may be extracted.

The auto- and crosscorrelation functions are shown in Figure 6.10,
and it appears that the noise elimination process is virtually
complete. The lower sample station autocorrelation deviates
somewhat from that of the PRBS signal as expected, the difference
being ascribed to dispersion effects in the bed and sampling
system as discussed above. Information in the tail of the
crosscorrelation is clearly lost - this is regarded as an
inherent system limitation.

It is interesting to compare the mean residence time of gas in the
bed as computed from the bed volume and volumetric flow with the
difference in first moments of the two curves in Figure 6.10.
Theoretically they should give the same result, viz.:

$$\frac{L_t \varepsilon_f}{U_o} = \bar{t}_{auto} - \bar{t}_{cross} \qquad (6.4)$$

The RHS of equation (6.4) as applied to the data in Figure 6.10
comes to 8.02 s, and after correction for differences in sampling
system dead and rise times this becomes 7.33 s. The corresponding
LHS value comes to 6.64 s, i.e. the two (independent) calculations
agree to within 11%. This is probably as good as might be expected
under the circumstances: similar data published in context of
the Shell Chlorine study (118) contains deviations of up to 21%.
In any event, closure to within a reasonable limit certainly
FIGURE 6.10   TYPICAL AUTO- AND CROSSCORRELATIONS

emphasises the fact that the data is consistent and reflects true system information.

The frequency response derived from this data is shown in Figure 6.11 as magnitude ratio and phase angle versus frequency. At frequencies beyond about 0.9 radians per second the response is seen to deviate from the trajectory established at lower fre= quencies - this type of deviation was interpreted as the upper frequency limit of useful information. A magnitude ratio of -12 dB or attenuation by a factor of about 4 is regarded as typical, and failure to obtain higher frequency information probably reflects once again an inherent system limitation in the form of dispersion in the sample lines and FID units.

Attenuation by a factor of about 4 appears to be typical for this type of experimentation. Everson (110) in fact produced very similar magnitude ratio plots for a system involving an absorption column and a radio-active tracer.

The reproducibility of the frequency response is effectively demonstrated in Figure 5.13. Despite differences in PRBS decision time, the three responses shown are remarkably close.

6.2.2 Model Fitting

Possibly the most critical step in the entire procedure is the actual fitting of a model to the experimental frequency data.
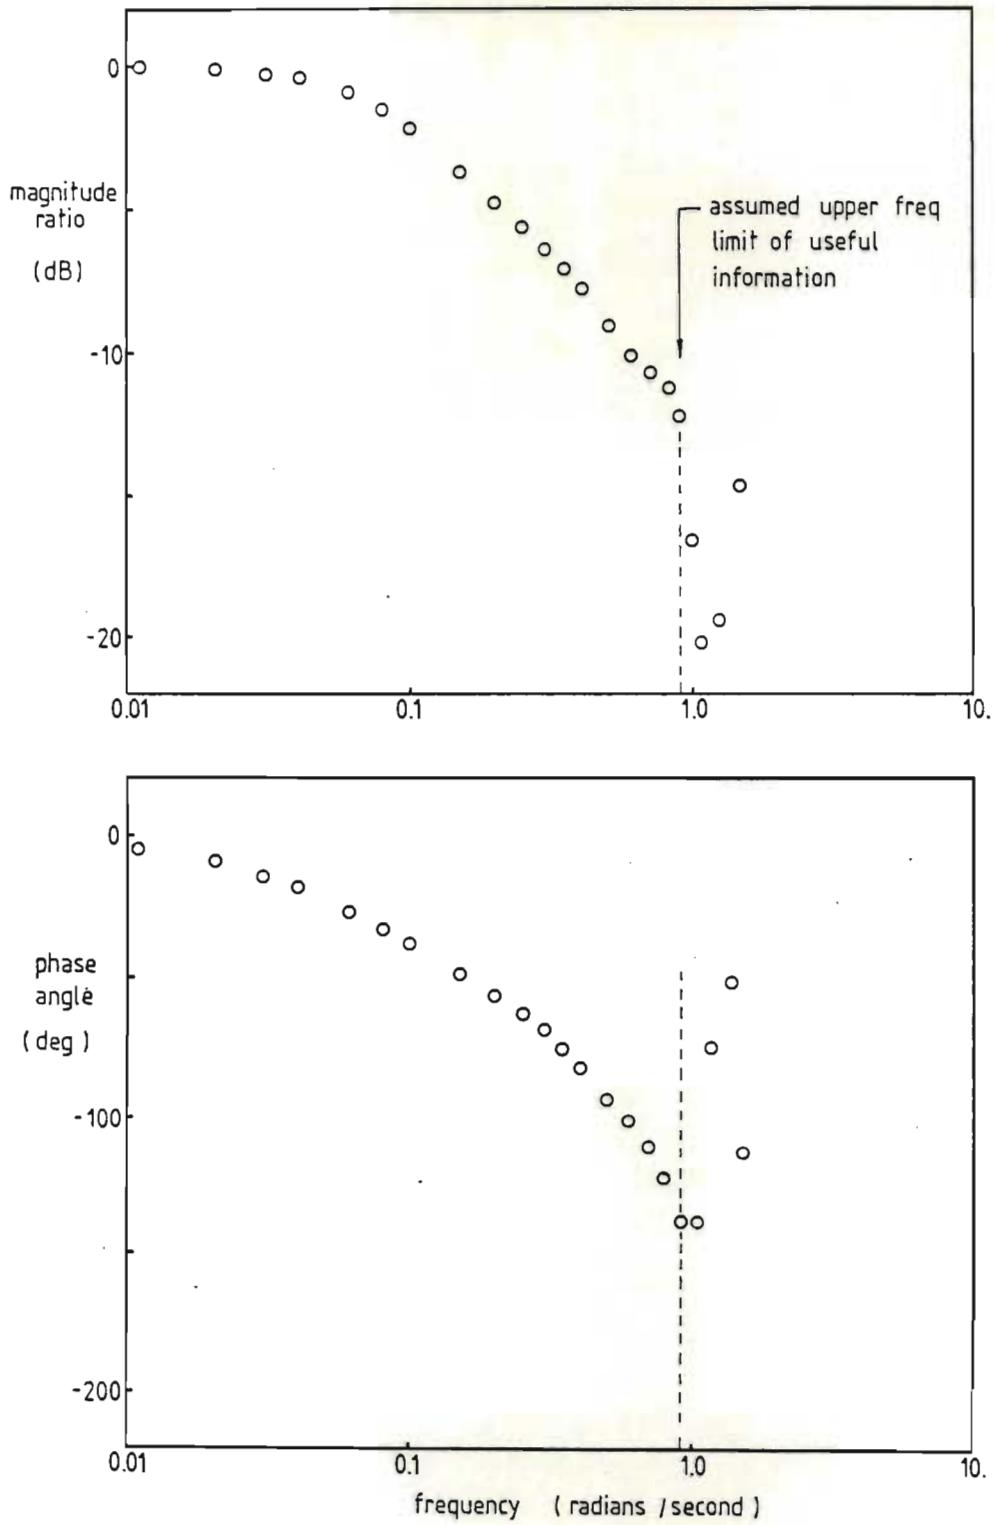

FIGURE 6.11   EXPERIMENTAL FREQUENCY RESPONSE

Each of the models considered contains two independent
parameters, and the simplex routine sets out to vary these in
such a way as to locate a minimum in the objective function.
This process may be viewed as searching for the lowest point
on a landscape defined by the difference between the model and
the experimental frequency response, with the two model parameters
as horizontal or ground co-ordinates and the objective function
describing vertical elevation. This landscape may be conveniently
depicted as a contour plot.

Certain requirements as regards the nature of this contour plot
must be satisfied in order to ensure full significance in the
result. Firstly, the parameter values at the optimum must be
physically plausible - for example, a negative crossflow ratio
would have no meaning. Secondly, the model parameters must be
uncorrelated. If the contours display an elongated furrow or
valley which does not run parallel to one or the other of the
model parameter axes, the chances are that the optimum will not
be unique. In other words, a range of pairs of parameter values
will satisfy the model fitting criteria equally well, and it will
not be possible in general to specify an exact value for either.

Contour plots for the five general models as applied to the
experimental data in Figure 6.11 are shown in Figure 6.12. The
contours for the MBT and MVD models are very similar as might
be expected from their formulation - both are more specific in
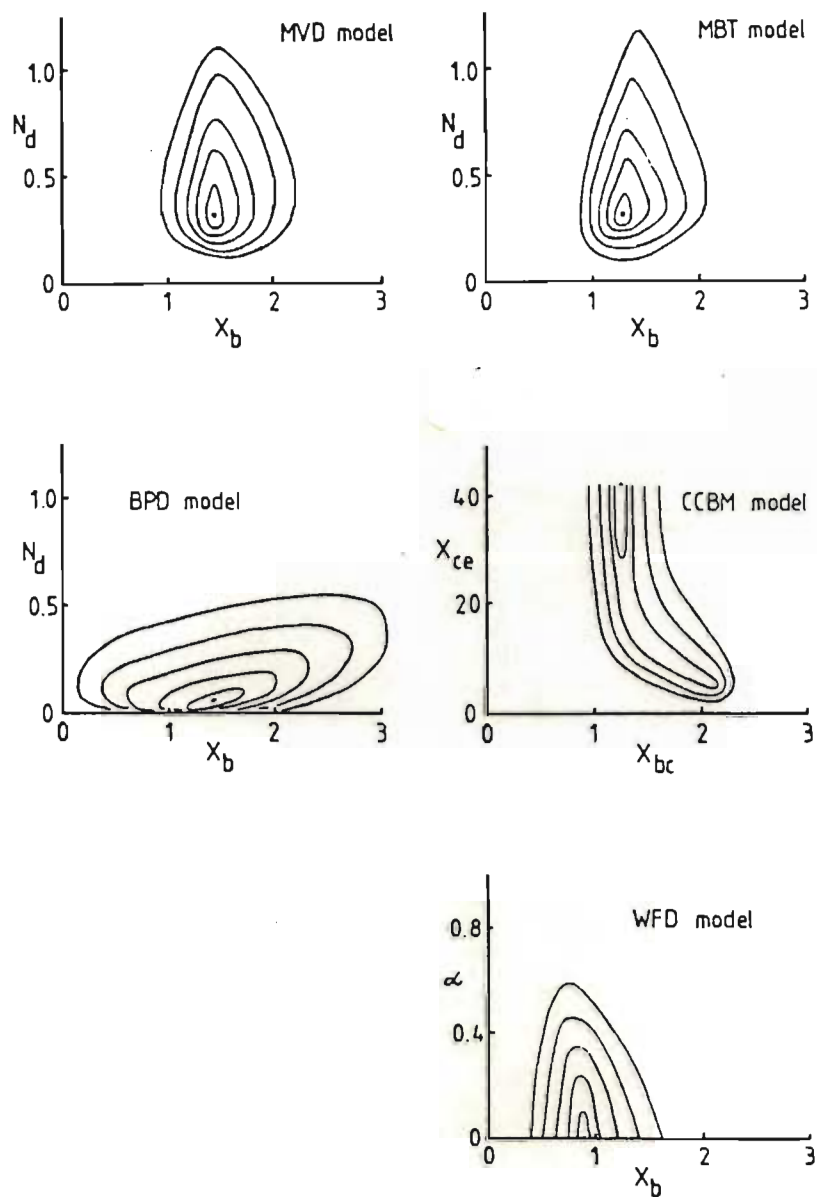

FIGURE 6.12   CONTOUR PLOTS FOR THE FIVE GENERAL MODELS

crossflow ratio than in dense phase dispersion number, and
the two parameters appear to be uncorrelated.

The BPD model contour plot reveals a very poor crossflow
sensitivity and a definite degree of correlation between cross=
flow and dense phase dispersion number. This may seem surprising,
but must be accepted in view of the model formulation and particu=
larly the boundary condition at a theoretically infinite bed
height.

The CCBM model contour diagram shows some correlation in the
region of low X_{ce} values, but this disappears at higher values
of this parameter and the system becomes very specific indeed to
X_{bc}. Beyond a certain value X_{ce} in fact ceases to influence the
optimisation, and an "optimum" is returned at whatever practical
upper limit imposed on this quantity.

The contour plot for the WFD model shows that the optimisation
is sensitive in X_b and converges on a zero α or cloud thickness.

Closure between the five models considered and the experimental
data is shown in Figure 6.13. On the co-ordinate system used
there is no clear distinction between the MBT and MVD model
frequency response profiles, and it is clear that these models
constitute a better process description than to the BPD, CCBM or
WFD models.
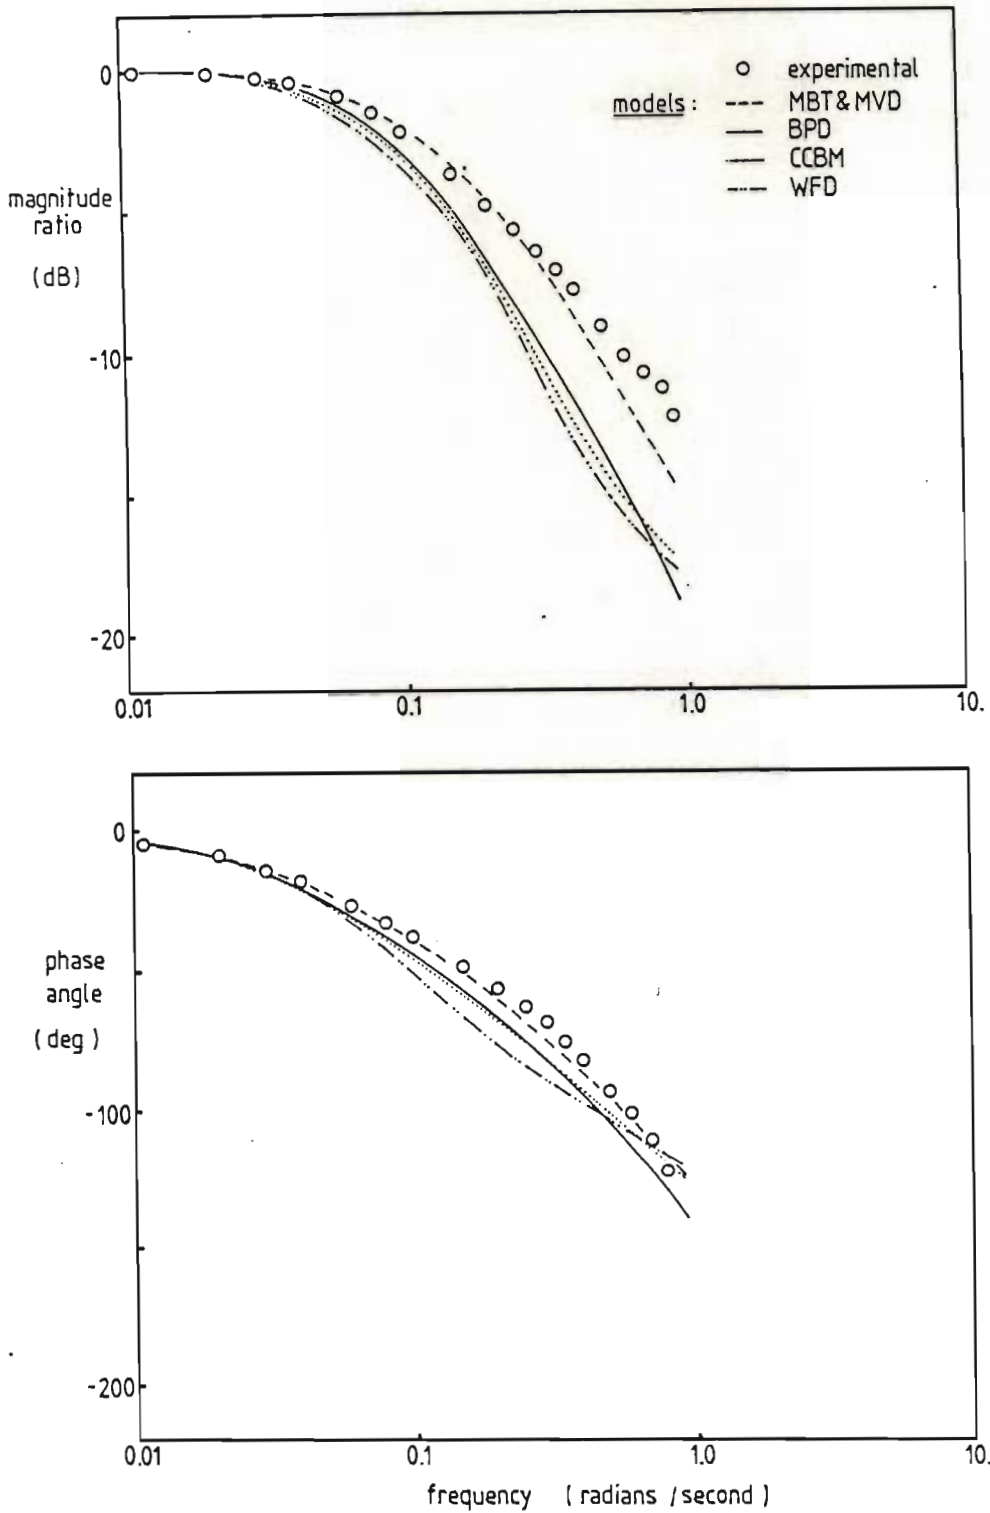

FIGURE 6.13 CLOSURE BETWEEN EXPERIMENTAL AND
MODEL FREQUENCY RESPONSES

In order to test the robustness of the parameters optimised
by the model fitting, it is necessary to examine the effect
of possible errors in the auxiliary parameters. If, for example,
average bubble velocity was out by 10%, how strongly would this
affect the estimated crossflow ratio?

The effect of a 10% variation in superficial velocity, average
bubble velocity and minimum expanded bed height is shown in
Table 6.1. The MBT model is employed for this sensitivity
analysis - the reason for this choice of model will become clear
later. The dense phase parameters ε_d and U_d are not included in
Table 6.1, since these auxiliary parameters were held constant
throughout the entire investigation.

An examination of Table 6.1 shows that errors in L_f are weakly
reflected in X_b, and that errors in U_b lead to similar errors in
X_b on a percentage basis. Errors in superficial gas velocity,
on the other hand, have a dramatic effect on the crossflow estimate.
This is not particularly disturbing, though, since U_o is measured
directly and large errors are not expected.

The dense phase dispersion number is far more sensitive to
auxiliary parameter errors than is the crossflow ratio. This is
very much in line with the MBT model contour plot in Figure 6.12 -
the optimisation procedure is more specific in X_b than in N_d. This

MODEL: MBT

PARAMETER VARIED	VALUE INCREASED BY	CORRESPONDING CHANGE IN X_b	N_d
U_o	+10%	-29%	-46%
	-10%	-70%	+193%
U_b	+10%	+7%	-24%
	-10%	-14%	-37%
L_f	+10%	-1%	-29%
	-10%	+1%	+37%

TABLE 6.1   SENSITIVITY ANALYSIS

is perhaps not too disturbing as far as this investigation is
concerned, since the aim is to measure X_b rather than N_d. The
statistical significance of values returned for N_d is clearly less
than that of values returned for X_b, so it would seem inappropriate
to attempt any meaningful analysis of this dense phase mixing
parameter.

6.2.3 Definition of an Error Index

Closure between a particular model and a set of experimental
data is reflected in the objective function value at the optimum
parameter combination. For one particular experimental fre=
quency response, objective function values for different models
provide a measure of which model best describes the system.
However, absolute objective function values do not consitute
a good basis for comparing closure on different experimental
frequency responses. The objective function value (at the
optimum model parameter combination) depends on the number of
frequency points involved, as well as on the spread. At very
low frequencies none of the models deviate significantly from
the experimental data; the greatest deviation occurs at some
higher frequency. There does not appear to be any obvious way
of ensuring that the objective function value for one set of
data is directly related to that of another.

A slightly different measure of the residual error between the
model and the experimental frequency response is called for.
One possibility is to define an index based on closure between
the best-fitting model and the experimental frequency response,
and to measure all the other models relative to this. This
approach was adopted in the present study, and an error index
(abbreviated EI) was defined as follows: the best-fitting model
for a particular experimental response is assigned an EI of unity.
The other models are then assigned indices given by the ratio

of the objective function minimum to that of the best-fitting

model. An EI of one is thus always present and associated with

the best model, and all the other model EI's are greater than

unity. This definition allows a meaningful average error index

to be computed for a single model over a number of experimental

frequency responses, since all runs are assigned an equal weight.

6.3   Model Screening

6.3.1   General Screening

The results of the general model screening are given in Table 6.2

in the form of average error indices, and a full breakdown of the

parameters and EI's is given in Appendix F. It should be noted that

MODEL	TUBE DIAMETER			OVERALL AVERAGE EI
	0.05 m	0.64 m		
		Coils	No coils	
MBT	1.12	1.02	1.02	1.06
MVD	1.25	1.05	1.03	1.13
BPD	3.55	6.23	10.28	5.55
CCBM	4.67	6.97	7.81	6.09
WFD	5.01	7.59	10.08	6.78
No. of runs	19	21	5	45

TABLE 6.2   GENERAL SCREENING ERROR INDICES

an average error index of unity implies that the particular
model fitted better than any other tried in every instance.

The results show that on average, the MBT model fits the
experimental data better than any other in both slugging and
bubbling units. The MVD model is clearly not far behind, and
the residual error obtained in fitting the other three models is
significantly greater.

The fact that a single model describes both bubbling and
slugging systems with the greatest degree of precision is
particularly gratifying. This result implies that the MBT model
reflects physical reality more faithfully than any other model
tested, and that the assumption of multiple plug flow units for
the bubble phase is sound.

The MBT model accounts for two phases only. This suggests that
the bubble cloud is indeed vanishingly thin as predicted by
Davidson's (17) bubble model, and this is supported by the fact
that the WFD model almost always returned a zero cloud thickness.
The other three-phase model, i.e. the CCBM model, commonly returned
an effectively zero cloud-emulsion mass transfer resistance,
particularly in the 0.64 m unit. This suggests that there is no
distinction between the cloud and emulsion phases, and further
supports the conclusion that only two phases are effectively present.

The behaviour of the BPD model is somewhat surprising. Poor
closure was obtained with data from the 0.64 m unit, and from
beds of about a meter of less in depth in the 0.05 m tube. For
a ca. 2.4 m bed in the 0.05 m tube, however, closure was in fact
better than that achieved by applying the MBT model. At a bed
height of about 3.5 m the situation was reversed once again,
but the BPD maintained a degree of closure similar to that of
the MVD model.

This behaviour could be interpreted as implying that the BPD
model adequately describes fully established slug flow. It is
not immediately clear why the formulation of this model should
be consistent with a slug flow situation, though rapid nose-to-
tail mixing of gas within the rather long slugs observed (0.3-0.4 m)
could conceivably be consistent with axial dispersion in the
bubble phase.

The performance of the WFD model is particularly disappointing.
This model is more tractable than any of the others, and even
a moderately better degree of closure with the experimental data
might have promoted its use in design and control. It could be
argued that, on the basis of Werther's (98) presentation of the
model, it should reduce to something similar to the MVD model for
a zero cloud thickness. This is not the case, however, since the
mathematical formulations of and solutions to these models are
quite different. In particular, it should be noted that the MVD

model solution is third order in z, whereas that of the
WFD is only first order.

6.3.2 Sparger Screening

Average error indices for the sparger screening are given in
Table 6.3, and a full breakdown is included in Appendix F as
before.

The laterally segregated bubble phase model describes the
results better than its mixed bubble phase counterpart in
every instance. This suggests that sparger bubbles tend to
retain their identity as they pass through the bed, i.e. that
coalescence effects between grid and sparger bubbles are not
very strong.

Conclusions of this nature should be regarded with caution, since
the argument is very indirect. However, the suggestion that
sparger bubbles retain their identity is consistent with the
bubble velocity axial dependence shown in Figure 6.7 - average
rise velocity of the sparger bubbles (below about 1.5 m above the
sparger) does not appear to be dominated by that of bubbles
rising from the grid.

6.4 Crossflow Ratio: The Effect of Vessel Geometry

In a fluidised bed containing a fine powder and operating at a gas
velocity of some tens of centimeters per second, the gas which enters
the dense phase from the grid directly is very small compared to that

MODEL	AVERAGE ERROR INDEX
LSBP	1.00

TABLE 6.3   SPARGER SCREENING ERROR INDICES

which enters in the form of bubbles. Under these conditions the hydrodynamic resistances may be considered to function in series, and in a reactor operating under conditions of interphase mass transfer control conversion would be related mainly to crossflow ratio. In a situation of this type reactant material which finds its way into the dense phase is rapidly consumed, and overall conversion is effectively dictated by the percentage of gas originally present in the bubble which is swept across the bubble-dense phase interface. Dense phase mixing is of secondary importance in situations of this nature, provided the reaction velocity constant is high enough to ensure rapid reaction despite possible dilution effects in the dense phase.

Mass transfer-limited conversion represents a kind of performance ceiling for a fluidised bed reactor. If, for example, a reactor is operated under conditions of kinetic control, overall conversion will be related mainly to the intrinsic reaction rate. The partial pressure or concentration term(s) in the kinetic expression will be affected by mixing in the dense phase, and crossflow will probably be of relatively minor importance. If the situation were now altered by decreasing the reaction resistance by (say) increasing the temperature, overall conversion would initially increase. However, a point would eventually be reached where the mass transfer limitation took effect, and further temperature increases would do very little to increase overall conversion. The performance ceiling would have been reached, and to improve performance further one would need to change the crossflow ratio, i.e. the hydrodynamics of the system.

Crossflow ratio is a very important parameter in scale-up.
If the pilot unit which serves as the basis for a demonstration
or full-scale design is mass transfer limited, it is vitally
important to ensure that the crossflow ratio in the large unit
is at least as high as it is in the small one if conversion is
to be maintained. If the pilot unit is not mass transfer limited,
it is still advisable to ensure that the crossflow ratio will be
high enough in the scaled-up reactor. It is quite conceivable
that, as vessel diameter increases, an interphase mass transfer
limitation not evident in the small unit could intrude and
seriously depress conversion.

The importance attached to X_b in scale-up also applies to the
evaluation of reactors with different internal geometries.
For example, what is the effect of introducing baffles or
cooling coils into the bed? If the system is mass transfer
limited, the resulting change in crossflow ratio will also
reflect the change in overall conversion. If the reactor is not
mass transfer controlled, the change in X_b will probably reflect
a change in performance ceiling rather than actual performance.

Overall, it is clear that crossflow ratio is probably the most
important parameter describing the hydrodynamics of a fluidised
bed. In this section the effect of scale-up and internal geometry
on crossflow is examined on the basis of the results from the
best-fitting model in each model category. The MBT model crossflow
ratios are employed in all cases barring those in which the

sparger was present, and those returned by the LSBP model
are used otherwise.

6.4.1 The Effect of Tube Diameter

Crossflow ratios obtained on the 0.05 and 0.64 m units are
shown in Figures 6.14 and 6.15 respectively. The general trends
are similar, and the strong dependence on superficial gas velocity
is understandable in terms of bubble residence time effects. The
superficial velocity effect appears strongest in a deep bed in
the 0.64 m unit - this is consistent with the bubble velocity
data given in Figure 6.3.

Crossflows are higher in the 0.05 m tube than in the 0.64 m unit.
A cross-plot of the data in Figures 6.14 and 6.15 (at constant
superficial velocity) is given as Figure 6.16, and this effectively
illustrates the extremely powerful scale-up effect inherent in the
system studied. According to the trajectories in Figure 6.16, a
4 m bed in the 0.64 m unit is equivalent to about a 0.2 m bed in
the 0.05 m unit (from a crossflow point of view).

Figure 6.16 also illustrates some general characteristics of the
system hydrodynamics. Firstly, most of the interphase transfer
occurs in the bottom meter or so of the bed. The design of the
gas distributor probably has a strong influence on the amount of
crossflow activity in this region, and the enormous difference
between the two units is probably typical of a porous plate versus
a multi-orifice device.

FIGURE 6.15   CROSSFLOW RATIO ON THE 0.64 m UNIT
FIGURE 6.16   CROSSFLOW RATIO vs BED HEIGHT: THE SCALE-UP
EFFECT

Crossflow activity in the upper regions of the bed appears
to be fairly low in both cases. The 0.05 m tube remains more
active, though this is probably a simple bubble/slug residence
time effect. The rather flat profile in the upper regions of the
large unit suggests that increasing the bed height would be of
little benefit, since a large increase would probably lead to
a marginal increase only in X_b.

6.4.2   The Effect of Vessel Internals

One of the first modifications attempted on the Brownsville units
was the introduction of baffles (1). The results do not appear
to have been very encouraging, and later dummy coils were installed
to reduce the hydraulic diameter of the reactors. This change
also appears to have failed to improve reactor performance to any
significant extent (1).

In this study, the effect of hydraulic diameter was tested by
running the 0.64 m unit with and without the (dummy) vertical
cooling coils. With coils in place the hydraulic diameter came
to 0.19 m, and with no coils essentially 0.64 m. To make the test
as sensitive as possible, it was necessary to run at the maximum
bed height the cold model would safely allow (i.e. a 3.05 m test
section and about a 3.5 m bed height).

The crossflow results are shown in Figure 6.17. It appears that
the presence or otherwise of coils has very little effect on
FIGURE 6.17   EFFECT OF VERTICAL COILS IN THE 0.64 m UNIT

interphase mass transfer, and this is certainly consistent with the performance of the Brownsville reactors. Physically, this result suggests that, even though a bubble velocity effect is evident as discussed previously, vertical coils do little to limit bubble size - this has in fact been observed by Botton (119) amongst others.

Figure 6.17, taken in conjunction with Figure 6.16, suggests that the upper regions of a large bed are inactive and insensitive to (all but radical) design changes. Furthermore, the presence of a strong axial gradient in crossflow activity possibly explains the failure of the hydraulic diameter concept as applied to fluidised beds. In this system at least, interphase transfer appears to be influenced largely by distributor design, and the geometry of the containing vessel in the upper regions is apparently of relatively minor importance.

6.4.3   The Effect of the Sparger

Crossflow between sparger bubbles and the dense phase as optimised on the basis of the LSBP model is illustrated in Figure 6.18. The general characteristics of this data are similar to those of the data shown in Figure 6.15, and a cross-plot at constant gas velocity is shown in Figure 6.19.

In Figure 6.19 crossflow ratios from two different model types are compared. The main difference, besides the presence or otherwise
FIGURE 6.18   SPARGER CASE CROSSFLOW RATIOS

gas velocity : 0.30 m/s

data :

FIGURE 6.19   CROSSFLOW PROFILES IN SPARGER-CONTAINING AND SPARGER-FREE BEDS

of a split feed system, is that axial mixing in the bubble phase is accounted for in one model and not in the other. The nature of the model affects the crossflow estimate, and it would seem fair to compare LSBP model crossflows with MVD rather than MBT model ones. However, since the MBT model is accepted as the basis for crossflow comparison (in all cases where the sparger is not present), a slightly different approach is called for.

The difference between crossflows determined by applying the MBT and MVD models may be regarded as a measure of the effect of accounting for axial bubble mixing. From the data in Appendix F an average difference of 6% in X_b is evident, i.e. the MVD model returns crossflows which are, on average, 6% higher than those returned by the MBT model. It would seem reasonable, therefore, to decrease the LSBP model crossflow estimates by this amount prior to comparing them to MBT data - this has in fact been done in the preparation of Figure 6.19.

The data in Figure 6.19 suggests that the sparger does not significantly affect the crossflow progression. A region of vigorous mass transfer activity immediately above the sparger is evident, and this is probably analogous to the grid region in the sense that the design of the nozzles is likely to have a strong influence on crossflow. The fact that a similar amount of mass transfer activity occurred near the grid and just above the sparger is not surprising, since the nozzle outlets on the two gas distribution systems were essentially the same.

In practical terms, the results in Figure 6.19 suggest that the sparger may be employed to move the principal reaction zone closer to the cooling coils without any anticipated change in the quality of gas-solids contacting.

6.5   Axial Dependence of the Mass Transfer Coefficient

The axial crossflow profiles shown in Figure 6.16 are characterised by rapid activity in the grid region and a slower rate of inter= phase transfer higher up.   It has been suggested that the design of the gas distributor is important in determining crossflow in the grid region, but no explanation of how interphase transfer and grid design are related is put forward.

Intuitively, one might expect some hydrodynamic property (describing mass transfer) to remain constant with bed height. Small bubbles are generated at the gas distributor, and these grow as they rise.   A strong axial profile in bubble to dense phase interfacial area must exist as a result, and a question which arises is: does this axial dependence explain the shape of observed crossflow profile?   If it does, one would expect to find an inter= phase mass transfer coefficient based on bubble to dense phase interfacial area to remain constant with bed height.

The data generated in this study does not allow a direct examination of bubble to dense phase interfacial areas, and certain assumptions are called for if an MTC based on interfacial area is to

be computed. Calculations of this nature do not prove anything, since they are not based directly on experimental observations. However, it is the intention of the author to show that the crossflow profiles generated in this study are at least consistent with the concept of an axially invariant MTC based on interfacial area.

6.5.1 MTC Based on Bubble Volume

By definition, crossflow ratio X_b is related to a mass transfer coefficient based on bubble volume:

$$(K_{be})_b = \frac{X_b U_b}{L_f} \tag{6.5}$$

This expression is inherent in the model formulations, and is understood to represent averaged or lumped quantities. More correctly, one could write:

$$\int_0^{L_f} (K_{be})_b \, (z) \, dz = (\frac{X_b}{L_f}) \int_0^{L_f} U_b(z) \, dz \tag{6.6}$$

The bubble velocity measurement technique employed in this study returns averaged or integrated quantities, and the RHS of equation (6.6) may be computed directly. Experimentation at different bed heights (with the application of a lumped parameter model at each stage) may therefore be regarded as measuring an integrated MTC for various upper limits of integration.

One way of extracting a local MTC profile from height-averaged data is to assume a form of z-dependence. The integrated form of

the assumed expression may be compared with the experimental
height-averaged data, and the former adjusted for maximum
closure. The local profile arrived at in this manner is not
unique - a different assumed form of dependence would clearly
yield a different result.

For practical purposes, however, it is probably sufficient to
employ an expression with good flexibility and reasonable
boundary conditions. At zero bed height, for example, one would
expect $(K_{be})_b$ to assume moderate to large values, but to tend to
neither zero nor infinity. At very large values of z, on the other
hand, $(K_{be})_b$ might be expected to tend to some constant value. An
expression which meets these requirements is:

$$(K_{be})_b \ (z) \ = \ a + b.exp \ (c.z) \tag{6.7}$$

where a, b and c are constants. This expression is in fact the
same as that employed for extracting a local bubble velocity profile
from height-averaged measurements (see Section 6.1.1.2). The main
difference is that in this case the constant a is expected to be smaller
than b.

Application of equation (6.7) to the data in Figure 6.16 with
constant optimisation by the simplex technique leads to:

$$(K_{be})_b \ (z) \ = \ 3.7 \ exp \ (-2.8 \ z) + 0.15 \tag{6.8}$$

for the 0.05 m tube, and

$$(K_{be})_b \ (z) \ = \ 1.37 \ \exp \ (-1.8 \ z) + 0.28 \qquad (6.9)$$

for the 0.64 m unit. $(K_{be})_b$ and z are in reciprocal seconds

and m/s respectively, and equations (6.8) and (6.9) are plotted

in Figure 6.20. The difference in grid region activity shows up

strongly, and beyond about 0.7 m above the distributor the bubbling

bed appears to be more active on a unit bubble volume basis. This

may seem surprising at first, but is shown in Section 6.5.3 to be

consistent with published literature results.

6.5.2   Bubble to Dense Phase Interfacial Area

The local bubble velocity profile inferred from height-averaged

measurements on the 0.64 m unit, as described in Section 6.1.1.2,

is given by:

$$U_b(z) \ = \ 3.24 - 2.38 \ \exp \ (-0.32 \ z) \qquad (6.3)$$

No direct measurement of bubble size is carried out in this study.

However, as discussed in Section 6.1.1.2, plausible bubble diameters

emerge if Davidson and Harrison's (19) bubble rise expression is

solved for d_b with $\phi = 1.5$-1.6. The selection of a value for ϕ is

rather arbitrary, and before proceeding it would seem worthwhile

to apply some kind of cross-check.

Davidson and Harrison's (39) expression for $(K_{be})_b$, in conjunction

with the proposed bubble size profile, should generate an MTC
FIGURE 6.20   AXIAL MTC PROFILES

profile at least roughly in accord with that in Figure 6.20.

Davidson and Harrison's expression:

$$(K_{be})_b = 4.5 \left(\frac{U_{mf}}{d_b}\right) + 5.85 \left(\frac{D^{0.5}g^{0.25}}{d_b^{1.25}}\right) \qquad (2.16)$$

for the conditions employed here ($\phi = 1.55$) becomes:

$$(K_{be})_b = 0.0003 \, d_b^{-1} + 0.033 \, d_b^{-1.25} \qquad (6.10)$$

where $(K_{be})_b$ and d_b are in reciprocal seconds and m respectively. This expression, applied to the bubble diameter profile shown in Figure 6.4 for $\phi = 1.55$, yields the MTC profile shown in Figure 6.21. The general shape is consistent with that obtained from crossflow data in the previous section, and the assumed bubble diameter profile may be considered reasonable on this basis.

Now if the bubbles are considered to be spherical, the ratio of surface to volume is given by:

$$S_b/V_b = 6/d_b \qquad (6.11)$$

In other words, interfacial area per unit bubble volume may be computed directly from a bubble diameter profile such as that shown in Figure 6.4.

A similar treatment for the 0.05 m unit is not possible since no axial dependence in bubble/slug velocity was observed. However, in the fully established bed, slugs of 0.3 m in length were typical. If a hemi-spherical cap and a flat base are assumed, the surface to volume ratio is of the order of 11 m^{-1}. This allows one to make a
FIGURE 6.21   CROSS - CHECK ON THE BUBBLE DIAMETER
PROFILE

rough estimate of an MTC based on interfacial area in the upper

regions of the slugging bed.

6.5.3 MTC Based on Interfacial Area

For the case of spherical bubbles:

$$(K_{be})_s = (K_{be})_b \, (d_b/6) \qquad\qquad (6.12)$$

For the 0.64 m unit $(K_{be})_b$ and d_b may be taken from Figures 6.20

and 6.4 respectively. Values for $(K_{be})_s$ at 0.05 m bed height

increments are shown in Figure 6.22, and it is immediately apparent

that this quantity (as computed here) does not vary with bed height.

For the case of fully established slug flow in the 0.05 m unit,

$(K_{be})_s$ may be estimated from:

$$(K_{be})_s = (K_{be})_b \, (1/11) \qquad\qquad (6.13)$$

For $(K_{be})_b = 0.15 \text{ sec}^{-1}$ as per equation (6.8) for z greater than

about 2 m, $(K_{be})_s$ comes to 0.0014 m/s as shown in Figure 6.22.

It is interesting to compare the above results with published

data. Bauer et. al. (120) recently measured $(K_{be})_s$ in a 1 m bed of

108 μ quartz sand by a residence time technique, and arrived at a

constant value of 0.0089 m/s. This quantity was shown to be

insensitive to the exact nature of the gas distributor, and its

numerical value agrees almost perfectly with the 0.64 m bed data

in Figure 6.22.
FIGURE 6.22   MTC BASED ON **INTER**FACIAL AREA

Sit and Grace (75) studied mass transfer in a 2-D bed of glass ballotini, and for the finest powder (90 μ) tested, obtained a value of $(K_{be})_s$ of 0.013 m/s. The coarser powders generally displayed larger MTC's as predicted by Davidson's (39) bubble model.

For slugging beds of 64 μ glass ballotini, Guedes de Carvahlo, King and Harrison (121) recently published data which suggests $(K_{be})_s$ = 0.0018 - 0.0032 m/s for 0.25 m slugs. For 101 μ particles and slugs of the same type their data may be interpreted as $(K_{be})_s$ = 0.0015 - 0.0019 m/s, and for both systems the MTC increased as slug length decreased.

The data in Figure 6.22 suggests that $(K_{be})_s$ is significantly smaller in established slug flow than in a freely bubbling system. This trend is evident in the data generated here, as well as in a comparison between the 101 μ ballotini data of Guedes de Carvahlo et. al.121) and the 90 μ ballotini data of Sit and Grace (75).

A tentative explanation for this is to be found in the flow field associated with a long slug. Streamlines are expected to run parallel to the side walls, and more perpendicular to the slug-dense phase interface in the regions of the nose and base only. In other words, the side walls of a slug could be fairly inert from a mass transfer point of view, and longer slugs consistent with a lower MTC (based on interfacial area).

The results in Figure 6.22 suggest that, in a bubbling bed, bubble to dense phase interfacial area or simply bubble size provides a sound basis for estimating crossflow. If a reasonable value for $(K_{be})_s$ is assumed, a bubble size/velocity growth expression which is known to apply to the system in question is effectively all that is required to compute crossflow ratios. The difficulty with this approach, however, is the fact that it relies on a class D model. The empirical or semi-empirical nature of these models make them unsuitable for general application, and in a situation of the type encountered in this study it would be necessary to actually measure bubble sizes. The time and effort involved would probably be similar to that required for obtaining RTD data, so there is no clear-cut advantage in this alternative approach.

The fact that bubble to dense phase interfacial area accounts for the observed axial profile suggests that coalescence plays a relatively minor role in the overall process. The frequency of coalescence is probably high in the lower regions of the bed, and a significant coalescence effect on mass transfer might be expected to confound attempts to explain the axial MTC profile on the basis of interfacial area.

The results in this study alone may not be regarded as firm evidence of the lack of a strong coalescence crossflow enhancement effect. However, when they are seen in conjunction with those of Bauer et. al. (120) and the observation by Sit and Grace (76) that coalescence enhances

mass transfer by a moderate 20-30% only, it seems reasonable
to suggest that an overpowering coalescence effect of the type
suggested by Pireira and Calderbank (77) is not in fact present
in systems of this type.

C H A P T E R   7

SUMMARY AND CONCLUSIONS

Five general fluidised bed models have been formulated in
the dynamic mode and solved analytically for frequency
response. Four of these have appeared in the literature in
one form or another, and the fifth is novel in that it employs
multiple plug flow units in parallel for the bubble phase.
Two special models, also considered novel, are formulated
and solved numerically to describe a fluidised bed containing
a sparger.

An experimental technique based on correlation analysis is
employed to measure gas residence time distributions in cold,
atmospheric fluidised beds. The data are processed to the form
of a frequency response, and the latter is compared with that of
each model in turn. A simplex technique is employed to adjust
two parameters per model for maximum closure with the experimental
data and the residual error for each (at the optimum parameter
combination) provides a means of isolating the best-fitting model.
The optimised parameters of this model are regarded as estimates
of those of the actual process.

Broadly speaking, the conclusions drawn from the results in
this study may be regarded as falling into two categories.
Firstly, the (model) fitting and screening is significant in

that it highlights some general characteristics of fine powder systems and how they should be modelled. The second category involves estimated crossflow ratios and implications for this particular system type. Conclusions in this category are rather specific in nature, and may be expected to apply only within a narrow range of particle types and vessel geometries.

7.1 General Conclusions on Modelling

1. For fine powders a two-phase model is more appropriate than a three-phase one. This is in accord with Davidson's (39) bubble model, and holds true for both bubbling and slugging systems. If a three-phase model is applied to a fine powder fluidised bed and parameter optimisation is carried out, either the cloud thickness or the cloud-emulsion mass transfer resistance will generally tend to zero.

2. For both bubbling and slugging beds the multiple bubble-track or MBT model provides the greatest degree of closure. This suggests that accounting for axial mixing in the bubble phase by employing multiple plug flow units in parallel is mechanistically more correct than employing a single plug flow unit.

3.   In the case where gas is sparged into an already
fluidised system, the laterally segregated bubble
phase or LSBP model provides a better description of
the process than does the laterally mixed bubble phase
or LMBP model.

4.   The axial crossflow profile in the larger of the cold
models is consistent with the concept of an axially
invariant mass transfer coefficient based on interfacial
area.

7.2 Specific Conclusions on Crossflow

1.   A very strong scale-up effect is evident in the system
studied. Crossflow drops sharply in going from a cold
model simulating a typical pilot plant unit to one
simulating a semi-works reactor.

2.   As expected (79, 81), most of the crossflow activity
occurs in the bottom meter or so in both units.

3.   The presence or otherwise of vertical coils in the
bed has little effect on interphase mass transfer. The
conventional concept of hydraulic diameter in single-

phase flow is probably not applicable to this system,
since most of the activity is controlled by the nature
of the grid rather than that of the containing vessel
higher up.

4. The crossflow profile is very flat in the region beyond
    about 1 m above the grid. This suggests that a deep bed
    would have little advantage over a relatively shallow one
    from a mass transfer point of view.

5. The introduction of gas into the bed via the sparger
    does not significantly alter the pattern of gas-to-catalyst
    contacting.

APPENDIX   A

AN ANALYSIS OF PUBLISHED MODELS IN TERMS OF THE PROPOSED
MODEL CLASSIFICATION

(i)   May's two-phase model (12) is a straightforward class A

model. Level 2a and RTD input is used to obtain a lumped

(level 3a) MTC, and the latter may be used to predict

conversion.

(ii) Davidson and Harrison's (39) bubble models, with plug

flow and well mixed dense phases respectively, represent

a two-stage approach. A constant bubble size is assumed

at level 2, and a class C model (based on Davidson's (17)

bubble model and Highbie's (23) penetration theory) is

employed to compute an MTC for non-interacting bubbles.

Bubble interaction and end effects are ignored, and a class A

model is used with level 2a input and this MTC to predict

conversion.

(iii) Kunii and Levenspiel's (28) bubble model follows almost

the same pattern as Davison and Harrison's (39) models.

A constant bubble size is assumed at level 2, and class C

models are used to predict a pair of MTC's. End effects

and bubble interactions are once again ignored, and a

three-phase class A model which calls for bubble-cloud and

cloud-emulsion MTC's is employed to predict conversion.

(iv) The countercurrent backmixing model (29) follows a pattern
      identical to that of the Kunii and Levenspiel (28) model.
      The only difference is that the class A model includes
      convection in the cloud and emulsion phases.

(v)   Werther's (98) model employes an empirical bubble growth
      expression, i.e. a class D model, and assumes a constant
      MTC per unit area of bubble-cloud interface as a class C
      model. The integration with respect to bed height to
      yield a lumped MTC is performed analytically, and a class A
      model is then applied. Bubble interactions and end effects
      are ignored.

(vi) Kato and Wen's (46) bubble assemblage model employes a
      class D bubble growth expression and a simple class C
      model based on the work of Kobayashi (122). Bubble interaction
      and end effects are ignored and a class B model, distributed
      in the axial co-ordinate, is used to arrive at a conversion
      prediction.

(vii) The modified bubble assemblage model of Peters et. al. (48)
      follows a path parallel to that of the original bubble
      assemblage model. Different class D and C models are
      employed and the gas flow distribution in the class B model
      is somewhat more complex, but the approach is identical.

(viii)   Weimer and Clough's (92) model of a fluidised bed

gasifier employs two class D models: a bubble growth

expression by Mori and Wen (62) and a jet penetration

correlation by Basov (80). The class C model for the

bubbling bed is that suggested by Kunii and Levenspiel (28),

and the grid region class C model is based on the work of

Behie and Kehoe (123). The overall mass balance model may

be considered class B, since the MTC is crudely distributed

in the axial direction. The MTC changes from a high (grid

region) tot a low (bubbling bed) value in a discontinuous

manner as discussed previously.

(ix)   The scale-up procedure suggested by Krishna (124) is based

on Darton's (41) bubble growth expression and Davidson's (17)

bubble model. An analytical integration with respect to bed

height is performed, and the bulk of the discussion revolves

around the resulting lumped MTC. A limiting height for

bubble growth h* is included in the model development, and is

carried through as a required input. This quantity represents

a level 2 data requirement.

(x)   The scale-up procedure employed in the Shell Chlorine Study

(117,118) involved, among other things, the extraction of a

lumped MTC from RTD data on the basis of a simple class A

model.

(xi)   The reactor characterisation studies by <u>Wippern et. al.</u>
        (50) involved the extraction of a lumped MTC from RTD
        data, based on a number of alternative class A models.

(xii)   The gas distributor study by <u>Bauer et. al.</u>(120) also
        involves the extraction,via a class A model, of an MTC
        from RTD data. This quantity is subsequently moulded
        to the form of an MTC per unit bubble-cloud interface on
        the basis of a class D bubble growth expression.

A highly popular experimental strategy is to perform an
experiment with a reacting tracer under steady-state
conditions, and to <u>measure</u> the conversion achieved. The
analysis of such data is usually carried out by assuming a
class A or B model and working backwards to calculate an MTC.
Some of the studies in which this approach has been employed are:

(xiii) In the <u>Shell Chlorine</u> study (117), conversions were
        measured for ozone decomposition. A simple class A
        model was applied, and the resulting lumped MTC used for
        scale-up.

(xiv)   <u>Miyauchi et. al.</u> (93) measured the conversion profiles
        of propylene in a system where propylene oxidation was
        in progress. A class B model was then applied in the
        form of a local Lewis-Gilliland-Glass plot (125), and an
        axially distributed MTC thus extracted.

Finally, it would seem appropriate to note that mechanistic bubble growth simulations such as those reported by <u>Allahwala, Singh and Potter</u> (126) may be regarded as class D models.

FOURIER TRANSFORM ROUTINE DEVELOPMENT AND TESTING

C1. DEVELOPMENT

For the conditions under which equation (4.5) is valid,
the transfer function is related to the time-domain stimulus
$C_{in}(t)$ and response $C_{out}(t)$ by:

$$G(jw) = \frac{\int_0^\infty e^{-jwt} C_{out}(t)dt}{\int_0^\infty e^{-jwt} C_{in}(t)dt} \qquad (C1)$$

$$\text{or} \quad G(jw) = \frac{\int_0^\infty C_{out}(t) \cos wt\, dt - j\int_0^\infty C_{out}(t) \sin wt\, dt}{\int_0^\infty C_{in}(t) \cos wt\, dt - j\int_0^\infty C_{in}(t) \sin wt\, dt} \qquad (C2)$$

The numerical evaluation of this expression is problematic.
Himmelblau and Bischoff (127) discuss this, and Law and Bailey (128.)
suggest that accurate evaluation of the integrals is the key.
The personal experience of the author has been that, in situations
of this nature, a major source of error lies in the truncation
of the time-domain data (i.e. the upper limit of the integrals)
at some arbitrary time. The data is often truncated for practical
reasons, and the selection of the truncation point is usually
subjective. When process noise is present, information in the
"tail" is lost and the choice of a truncation point may be
particularly difficult.

The FT routine developed here inforporates the following features to minimise these effects:

(i) The numerical integration is performed by a double application of Simpson's Rule. The first integration is by exact fit second order polynomials on pairs of adjoining "strips", i.e. a conventional application of Simpson's Rule. The second is by third order exact fit polynomials to the three strips at either extreme, and second order poly= nomials to the intermediate pairs. The idea of the second application is to group strips which have not been paired in the first application. An average result is taken, and the overall effect is that of interpolating between overlapping second order exact fit polynomials.

(ii) Truncation is eliminated by fitting an exponential decay tail to the last 20% of the data by least squares, as shown in Figure C1. Analytical integrals based on this fitted decay tail are applied between t_f and infinity, the form being:

$$\int_{t_f}^{\infty} a_1 e^{-a_2 t} \sin (wt) \, dt = \frac{a_1 e^{-a_2 t_f}}{w^2 + a_2^{\;2}} \left[w \cos (wt_f) - a_2 \sin (wt_f) \right] \quad (C3)$$

$$\text{and} \int_{tf}^{\infty} a_1 e^{-a_2 t} \cos (wt) \, dt = \frac{-a_1 e^{-a_2 t_f}}{w^2 + a_2^{\;2}} \left[a_2 \cos (wt_f) + w \sin (wt_f) \right] \quad (C4)$$
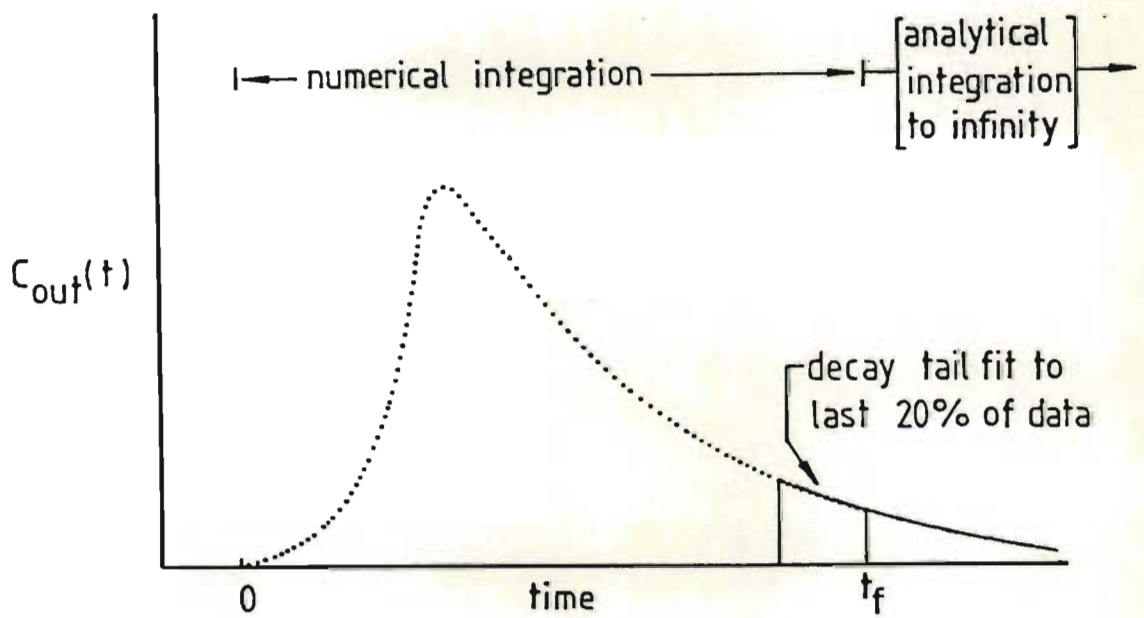

FIGURE C1   DECAY TAIL FIT AND INTEGRATION PROCEDURE

C2. TESTING

The Fourier Transform routine was tested against a simple
tanks-in-series model. The theoretical time-domain impulse
response for two perfectly mixed tanks with time constants
τ_1 and τ_2 is:

$$E(t) \;=\; \frac{1}{\tau_2 - \tau_1} \left(\exp\left(-t/\tau_1\right) - \exp\left(-t/\tau_2\right) \right) \tag{C5}$$

and the magnitude ratio of the corresponding frequency
response:

$$\left| G(jw) \right| \;=\; \frac{1}{\sqrt{1+(w\tau_1)^2} \; \sqrt{1+(w\tau_2)^2}} \tag{C6}$$

The discrete, truncated impulse response data given in Table C1
was supplied to the FT routine, and the ability of the latter
to generate the frequency response given by equation (C6) tested.
The time constants were fixed at 5 and 0.2 seconds.

The theoretical and numerical magnitude ratios are given in
Figure C2. It is clear that the FT routine performs extremely
well, even at frequencies well above those encountered in this
study.

AUTO AND CROSSCORRELATION CALCULATION DETAILS

Equations (5.6) and (5.7) may be re-written in a form more
suitable for numerical evaluation as follows:

$$R_{Y_1 Y_1}(i) = \frac{1}{n-i+1} \sum_{k=1}^{n-i+1} Y_1(k) \, Y_1(k+i-1) \tag{E1}$$

$$\text{and} \quad R_{Y_1 Y_2}(i) = \frac{1}{n-i+1} \sum_{k=1}^{n-i+1} Y_1(k) \, Y_2(k+i-1) \tag{E2}$$

It is understood that the time records are sampled at a
constant frequency, and that one sampling period is
associated with each increment in the counters i and k.

The calculation steps are:

(i)   Normalise the data by letting

$$Y_1(k) = Y_1(k) - \frac{1}{n} \sum_{l=1}^{n} Y_1(l) \tag{E3}$$

$$Y_2(k) = Y_2(k) - \frac{1}{n} \sum_{l=1}^{n} Y_2(l) \tag{E4}$$

(ii)   Compute the forward auto- and crosscorrelations
by applying equations (E1) and (E2).

(iii)   Compute the backward crosscorrelation (negative

time lag) as follows:

$$R_{Y_1 Y_2}(-i) = \frac{1}{n-i+1} \sum_{k=1}^{n-i+1} Y_1(k+i-1) \, Y_2(k) \qquad (E5)$$
